Date of Defense : 25 August 2014

To my dear family,

FOREWORD

I would like to sincerely thank and appreciate to my supervising professor, Dr. Christos Kassapoglou for his guidance, support, and encouragement throughout my research in every aspect. My gratitude goes to the committee members: Sonell Shroff and Dr. Halit S. Türkmen, for providing guidance and support.

Most of all, thanks to my family and Fatma Nur Evren, for their love, support, and encouragement. Without their love and support, none of this research work would have proceeded.

Finally, I would like to thank everyone from TU DELFT Composite Lab who have helped me with my research.

August 2014

Onur COŞKUN
(Aeronautical Engineer)

FINITE ELEMENT ANALYSIS, OPTIMUM DESIGN AND COST-EFFECTIVE MANUFACTURING OF ADVANCED COMPOSITE GRID-STIFFENED STRUCTURES FOR AIRCRAFT FUSELAGE APPLICATIONS

SUMMARY

Structural concepts being used for aerospace vehicles are searching for the most efficient ways by pushing the limits of their current time. In general, the meaning of stiffening imply that longitudinal stringers and frames or ribs are placed orthogonal or by some angle to the stringers. The main purposes of this application for structures are high stiffness to weight ratio, increase of bending stiffness preventing from local flutter, vibration and buckling, suitable for structural attachments and non-structural items.

Advanced Grid Stiffened (AGS) structures possesses wide variety of possibilities to design and manufacture stiffeners with different spacing, nodal offset, stiffener angle, number of stiffener, thickness of the skin, etc. AGS structures, which have complex component geometries, require the use of finite element analysis techniques for detailed structural analysis. Analytical methods cannot predict the local stress distributions and local failure types. Failure types of composite AGS structures under in-plane loads and under the effect of out of plane shear loads are categorized as five dominant failure modes. These are; instability of total panel, which is referred to as global buckling, local skin buckling, local buckling or crippling of the stiffeners, material failure and delamination caused by inter-laminar shear stresses. Understanding the failure behavior and stress distributions on the composite AGS panel under inplane loading and the effect of out of plane shear loads is important to structural design. Thus, all five different failure modes and stresses at critical locations like nodes of AGS panel are considered in the design and need to be considered in validation and certification phases.

AGS panel is modeled and analyzed using 2D quadrilateral elements using MSC Patran/MSC Nastran. Stress distributions along the stiffeners and the skin can be separately taken from their element centroids and different buckling modes of the AGS panel can be observed using SOL105. MSC Patran PCL functions are used to change the stiffener spacing. An optimization cycle is set-up using MSC Nastran SOL200 solver, which takes into account stiffener crippling and material failure as design constraints. The inter-laminar shear stresses along the height of the stiffener and at the skin-stiffener interface section is taken from local 3D model of highly stressed regions.

The decision is made for the optimized panel under mixed loading, which is shear-bi-axial compression respectively 175 N/mm and 60 N/mm -150N/mm. According to optimization results, stiffener height is 21.377 mm, stiffener spacing is 205.8 mm.

The manufacturing of the AGS panel, which is laborious with any technique done in previous studies, is accomplished successfully by using Vacuum Assisted Resin Transfer Molding like technique. The integral manufacturing of grids and skin using resin infusion provides low-cost manufacturing of AGS panels. In this process, pattern of the grids are printed using 3D printers and silicon rubber, which takes the shape of printings, which are used to make mold, then fibers are laid into the grooves. After laying all the fibers, which can reach 50% percent fiber fraction just by hand process, skin is put on the side where fibers are ending. After resin infusion, composite AGS panel is cured at elevated temperature in the oven.

GRID TAKVİYELİ İLERİ KOMPOZİT YAPILARIN UÇAK GÖVDESİ İÇİN SONLU ELEMANLAR ANALİZİ, OPTİMUM TASARIMI VE UYGUN MALİYETLİ ÜRETİMİ

ÖZET

Uçak ve uzay yapıları için geliştirilen ve içinde bulunduğumuz zaman dilimine ile paralel teknolojik gelişmeler ile uygulanabilen üretim yöntemleri her geçen gün daha da ilerlemektedir. Bu ilerleyişin ve artan araştırmaların doğal bir sonucu olarak kompozit malzemeler ve bunlardan oluşturulan yapılar metal, alüminyum gibi malzemelerin yerini almaktadır. Grid Takviyeli İleri Kompozit yapılar ise bu malzemelerle geliştirilmiş farklı tasarım ve üretim yöntemleri ile ortaya çıkmıştır. Genel anlamı ile grid takviye, boyuna kirişler halinde ortogonal veya çeşitli açılarla yerleştirilmiş yapılara denmektedir. Yapılarda bu tür bir kompozit yapının kullanılmasının başlıca nedenleri yüksek sertlik-ağırlık oranı olması, eğilme rijitliğini artırarak bölgesel flutter, titreşim ve burkulmayı önlemesi, yapısal eklemelere ve yapısal olmayan öğelere uygun olması.

Grid Takviyeli İleri Kompozit yapılar tasarım ve üretim açısından birçok çeşitliliğe olanak vermektedir. Bu çeşitlilik kirişlerin açıklığı, düğüm noktası kaçıklığı, kiriş açısı, kiriş sayısı, yüzey plakasının kalınlığı, vs. ile sağlanabilmektedir. Bu tip karmaşık değişkenlere sahip olan bu sistem şu an için analitik olarak tam çözülememektedir. Bu nedenle sonlu elemanlar analiz yöntemleri ile modellenip detaylı bir analize ihtiyaç duyulmaktadır. Bu ihtiyacın da ana nedeni lokal gerilme dağılımlarının ve lokal kırılma ve kopmaların incelenebilmesidir.

Grid Takviyeli İleri Kompozit yapılar çeşitli kırılma tiplerine sahiptir. Bunlar, düzlem içi yükler ve düzlem dışı kayma gerilmelerine bağlı olarak beşe ayrılabilirler; tüm panelin kararsızlığına yol açan burkulma davranışı, lokal yüzey burkulması, lokal kiriş burkulması, malzeme kopması ve tabakalar arası kayma gerilmesinden kaynaklanan tabakalar arası kayma davranışlarıdır. Yapısal tasarım açısından kırılma davranışının ve gerilme dağılımlarının Grid Takviyeli İleri Kompozit malzemeler için bilinmesi önemli bir parametredir. Bu önemin nedeni, kritik noktalardaki beş farklı kırılma mekanizması tasarımda olduğu kadar aynı zamanda onaylama ve sertifikasyon süreçleri içinde göz önünde bulundurulması gerekliliğidir.

Grid Takviyeli İleri Kompozit yapı 2 boyutlu sonlu elemanlar yöntemi kullanılarak dörtgen elemanlar kullanılarak modellenmiştir. Bu elemanlar MSC Patran/Msc Nastran adlı ticari program içerisinde tanımlanmış olan eleman tipleri kullanılarak yapılmıştır. Yapılan modellemede klasik yöntemlerin aksine kirişlerin olduğu yerlerde çift eleman kullanılmış ve bu şekilde gerekli olan katılık 2 boyutlu olarak tanımlanabilmektedir. Bu tasarım tüm boyutlandırmalar tanımlandıktan sonra yapılabilir, başka bir deyişle sadece kiriş ve yüzey kalınlığı program içinden girilen değerler ile değiştirilebilmektedir. Bunun haricinde yapılması gereken boyut değişimleri MSC. Patran PCL fonksiyonları kullanılarak yapılmıştır.

MSC. Patran PCL fonksiyonun en önemli işlevi makro gibi çalışabilmesi ve bu sayede her defasında belirli değerlere kadar olan kiriş açıklığı değişimleri için sonlu elemanlar örgüsünü Mathematica’da yazılan kod sayesinde yeniden yaratabilmesidir.

Grid Takviyeli İleri Kompozit yapı için 3 boyutlu sonlu elemanlar yöntemi kullanılarak da modellenmiştir. Bu modelleme ile tabakalar arası kayma gerilmesinden kaynaklanan tabakalar arası kayma davranışı olup olmadığı karbon fiber destekli plakalarda 50 MPa gerilme değeri ile karşılaştırılıp karar verilmektedir. Bu yöntemdeki sınır koşulları 2 boyutlu modelde kritik olduğuna kara verilen bölgeler için eşdeğer eleman genişliğinde yapılan 3 boyutlu modele 2 boyutlu analiz sonuçlarından gelen öteleme ve dönme hareketinin uygun düğüm noktalarına uygulanması ile tanımlanmıştır.

Grid Takviyeli İleri Kompozit yapı için 2 boyutlu sonlu elemanlar yöntemi kullanılarak gerilme ve burkulma analizleri yapılmıştır. Bu analizler için Nastran SOL101 ve SOL105 kütüphaneleri kullanılmıştır. Yapılan modelleme tekniğiyle birlikte kirişlerin ana yük taşıyan fiber doğrultusu boyunca gerilme değişimleri gözlemlenmiş ve tasarım hakkında genel bir gözlem yapılabilmektedir. Yüzey üzerindeki gerilme değişimleri ile ona bağlı olan kirişlerdeki gerilmeler karşılaştırılmış ve mantıklı bir fizik davranışı elde edilmiştir. Burkulma analizlerinde ise yapı farklı yükleme koşullarında incelenip, nihayetinde en kritik olan yükleme koşulu için 10 farklı burkulma modu incelenmiştir. Bu inceleme sonucunda gerçekleşen burkulmaların sadece lokal yüzey hücre burkulmaları olduğu gözlemlenmiştir. Nastran’ın hesapladığı özdeğer vektörü 1. mod için 1 değerine yaklaşıktır. Bu da demek oluyor ki bu yükleme koşulu 2 için ilk mod aynı zamanda kırılma gerilmesinin de olduğu yük durumuna karşılık gelmektedir.

Grid Takviyeli İleri Kompozit yapı için 2 boyutlu sonlu elemanlar yöntemi kullanılarak optimizasyon analizleri de yapılmıştır. Bu analiz için Nastran SOL200 kütüphanesi kullanılmıştır. Tasarım kısıtları olarak malzeme kırılması, lokal kiriş burkulması ve Euler burkulması referans olarak alınmıştır. Yapılan optimizasyon çalışması Nastran’ın kendi içerisindeki algoritmaları kullanması ile gerçekleştirmiştir. Burada “hard convergence” denilen bir yakınsama metodu ile denklemler iterasyonlarla çözülmektedir. Her döngüde elde edilen yakınsaklık değerleri ile tüm sonlu elemanlar modeli yeniden çözülmekte ve en son iterasyona kadar bu süreç devam etmektedir. Yapılan bu çalışma sonucunda, verilen yükleme altında 2 boyutlu gerilme analizi için kullanılan model kullanılmış olup, optimum boyutlar elde edilmiş ve bunların yukarıda anlatıldığı gibi ayrıntılı analizleri yapılmıştır.

Grid Takviyeli İleri Kompozit yapı için üretim yöntemi de geliştirilmiş olup başarılı bir şekilde uygulanmıştır. Bu üretim yöntemi daha çok literatür üzerinden yapılan çalışmalar üzerinden yola çıkılarak geliştirilmiştir. Vakum destekli reçine infüzyonu ile yapılan üretim silikon kalıplar içerisinde gerçekleştirilmiştir. Kullanılan silikon kalıplar belirli noktalarından delikler açılarak reçine ile beslenmiştir. Açılan bu delikler direkt olarak kirişlerin yatırıldığı boşlukların olduğu kısımlara açılmıştır. Gösterge basını 55 mbar olarak ayarlanıp reçinenin kurulan düzenek içinde ilerlemesi sağlanmıştır. Yüzeyde ve kirişlerin içinde ilerleyen reçine kalıbın bittiği noktalarda dışarı çıkmaması için yarı geçirgen bir zar ile örtülmüştür. Bu zar hava akışını sağlamakla beraber reçine gibi sıvı bir maddenin geçişine izin vermemekte ve bu şekilde reçine içeride kalmakta ve bütün fiberler boyunca bir dağılım gösterip en kolay bulduğu yoldan dışarı kaçmamaktadır.

İnfüzyon işlemi yapıldıktan sonra malzeme düzeneği aynı vakum altında fırınlanmakta ve 5 saat sonra çıkartılıp silikon kalıptan çıkarılmaktadır. Bu yöntem ilk olarak tek hücre yapısı için denenmiş olur daha sonra 2*2 hücre için denenmiş ve elle yatırma işlemi nedeniyle daha fazla hücre sayısı için otomasyon yöntemlerin kullanılmasına karar verilmiştir. Bu başarılı üretim sonuçlarından sonra yapı makro boyutlarda çekim yapan bir kamera ile incelenmiş ve kuru veya fiber çekme kuvvetinin kaybı ile oluşmuş üretimden gelen hatalar tespit edilmiştir. Ayrıca reçinenin düğüm noktalarında fiber hacminin artması sonucu nasıl dağıldığı gözlemlenmiş ve literatür üzerindeki çalışmalarla kıyaslanmıştır.

1. INTRODUCTION

1.1 Background

Structural concepts being used for aerospace vehicles are searching for the most efficient ways by pushing the limits of their current time. Early developments on composite structure designs imitated the configurations similar to those of metal counterparts. Composite Grid Stiffened Structures are the one of the replacement for Honeycomb Sandwich and Aluminum Isogrid constructions but, till the past 10 years, were unused due to difficulties in manufacturing and analysis associated with their construction (Rehfield and Deo, 1978; Huybrechts et al, n.d; Niu, 1992)..

In general, the meaning of stiffening imply that longitudinal stringers and frames or ribs are placed orthogonal or by some angle to the stringers. The main purposes of this application for structures are high stiffness to weight ratio, increase of bending stiffness preventing from local flutter, vibration and buckling that is suitable for structural attachments and non-structural items. Using much the same principle to strengthen the structures, grid stiffened structures have been widely used in engineering structures since the nineteenth century, such as aircrafts, ship hulls, autos, offshore oil platforms, bridge decks, armors, etc. Composite grid stiffened structures, which are characterized by a lattice of rigid and interconnected ribs, can be used where honeycomb sandwich and aluminum isogrid constructions are needed (Rehfield and Deo, 1978; Huybrechts et al, n.d, 1995).

Isogrid type of stiffening, which possesses the same advantages, is an alternative approach to traditional concept. The first isogrid panel, which is the precursor of the Advanced Grid Stiffened (AGS) structure, is manufactured and patented by the McDonnell-Douglas Corporation in 1964 under NASA contract. These types of structures behave as an isotropic within the plane of structure and they are mainly used for launch vehicle shroud and inter-stages. Early composite isogrid structures were manufactured for aerospace applications had very low fiber volume fraction and poor part quality. In the early 1990s, the Air Force Phillips Laboratory

manufactured isogrid structure using tooling made of silicon rubber and achieved high quality and high strength-weight ratios .

The interest for composite grid stiffened structures was decreasing for many decades due to complex manufacturing and analysis technique needed for application. In recent years, the Boeing Company, the US Air Force Research Lab, McDonnell-Douglas, Alliant Tech Systems, Stanford University, and others have made some researches and publications with the aid of developing technology on computation and manufacturing. They are now currently being investigated by several aerospace structure manufacturers (Rehfield and Deo, 1978; Huybrechts et al, n.d).

Isogrid pattern, which consists of equilateral pattern, has been optimized and changed its shape for specific loading situations in past few years. With the new applications, the prefix “iso” is replaced by Advanced Grid Stiffened (AGS) structure patterns. The source of increasing interest on composite materials for the grid stiffened panel is the high directionality of composite materials. The high directionality allows material’s stiffness to be directed along the critical direction and a substantial increase in the stiffener strength along rib length (Huybrechts and Tsai, n.d, 1995). The several types of the grid stiffened structure can be seen in Figure 1.1.

Figure 1.1: Types of grid-stiffened panels.

Composite grid stiffened structures are manufactured using fiber and matrix composition. The difference of these structures from the traditional composite panels is the shell structure supported by a lattice pattern of stiffeners. These stiffeners follow different directions according to desired stiffness and strength properties. Nodes are the points where two or more ribs intersecting each other. If more than two ribs intersect at the same node, an offset needs to be applied for to reduce the build-up on that node in manufacturing phase. The distance between the new node and the previous node is referred to as nodal offset (Huybrechts and Tsai, n.d, 1995).

Benefits of composite grid stiffened structure can be listed as given below:

- Higher damage tolerance than the honeycomb sandwich and in case of delamination limiting its spread to another cell,
- The absence of material mismatch, which is associated with laminated structures, provides inherent resistance to impact damage, delamination and crack propagation (Huybrechts and Tsai, 1995),
- Grid structures do not absorb and retain water in service life due to its open structure unlike honeycomb sandwich structures,
- Automated and single cure process result in low-cost manufacturing if it is compared with skin stringer and sandwich construction. Continuous filament winding, tape placement and resin transfer molding (RTM) using a woven preform have been applied to composite grid structures ,
- The repetitive pattern aids to minimize manufacturing costs by effective use of equipment (Slysh, n.d),
- Integral panel manufacturing methods aims to reduce part assembly, handling, and inventory costs by reducing the number of structural parts (Slysh, n.d),
- Higher in-plane stiffness provides structural efficiency to prevent from excessive deflections (Huybrechts et al, n.d),
- Fabrication process for grid structures may not require de-bulking or use of an autoclave, reducing the costs considerably (Huybrechts and Tsai, 1995).

Drawbacks of composite grid stiffened structures can also be listed as given below:

- Complex structural behavior of grid structures, thus unpredicted failure,

- Complex tooling requirements may increase the cost for unique parts and small number of productions (Huybrechts et al, n.d).
- The irregularities can be faced with a composite grid stiffened structure; soft and hard points in the grid lattice, damaged grid lattice and repairing process to this lattice, areas where two or more grid structures are joined together which causes fiber accumulation (Huybrechts and Tsai, 1995).

1.2 Objectives and Approach to the Thesis

Composite AGS structures, which have complex component geometries, require the use of finite element analysis techniques for detailed structural analysis. In most instances, analytical methods cannot predict the local stress distributions and local failure types. Thus, commercial finite element analysis (FEA) program with different type of finite element formulations, which satisfy the expected behavior composite elements, can be used to analyze the effect of the critical loading conditions. In addition to that, analytical approaches can simultaneously be used to simplify FEM method to imitate the physical behavior.

The physical behavior of the designed composite AGS structure should take into account all the possible failure modes that can be faced during service life of the structure. Therefore, it is necessary to define failure types of composite AGS structures under in-plane loads and the effect of out of plane shear loads. These failure behaviours can be categorized as five dominant failure modes (Gallagher, 1971).

The first failure mode is the instability of total panel, referred to as global buckling, which causes skin and stiffeners deflect out of plane direction. Buckling strength of the plate is defined by the load at this critical point. Buckling deformations may result in collapse, if the load at the initiation of the buckling continues increasing unrestrainedly (Gallagher, 1971).

The second failure mode, local skin buckling may occur if the skin between the stiffeners deflects more than covering stiffeners. The reason for this mode is the stiffener resistance to bending, due to high bending stiffness of the stiffeners. This local instability of the AGS panel is preferable to the global buckling (Kassapoglou, 2013).

The third failure mode is the local buckling or crippling of the stiffeners. This stability failure causes a local buckling and then collapse of the stiffener. It should be noted that after the collapse of the stiffener loads can be carried by the other members of the AGS structure (Kassapoglou, 2013).

The fourth failure mode is material failure, where the strength of the material in the skin or stiffener is exceeded. This failure mode is depended on the laminate lay-up and the loading conditions (Kassapoglou, 2013).

The fifth and final failure mode considered is delamination caused by inter-laminar shear stresses. Delamination may occur separately in skin and stiffeners or at the surface layer where skin and rib facing with each other. In this mode, the layers of the material separate from each other and the AGS structure could lose strength and stiffness properties and may lead to a catastrophic failure (Kassapoglou, 2013).

Understanding the failure behavior and stress distributions on the composite AGS panel under in-plane loading and the effect of out of plane shear loads is crucially important to structural design. Thus, all five different failure modes and stresses at critical locations like nodes of AGS panel have to be considered in the design, validation and certification phases (Kassapoglou, 2013).

The main objectives of this thesis to:

- Model AGS panel using Finite Element (FE),
- Analyze of stresses on AGS panel in detail using FE,
- Optimize the AGS panel for robust load case according to failure modes for minimum weight,
- Develop a method for AGS panel manufacturing using resin infusion system,
- Evaluate the manufactured AGS panel quality.

1.3 Scope

AGS structures possesses wide variety of possibilities to design and manufacture stiffeners with different spacing, nodal offset, stiffener angle, number of stiffener, thickness of the skin, etc.

This thesis is limited to some key issues, which narrow down structural behavior and the manufacturing to be understood without difficulty, due to complex property of AGS structures.

These limitations include:

- AGS panel consists of perpendicular longitudinal (x-axis) and horizontal (y-axis) stiffeners, and angled stiffeners that cross x-axis with ± 35 degree and $[+45/-45/0/0/0/90]_s$ configuration for the skin lay-up,
- FE design and analysis of the composite AGS panel is conducted using Msc. Patran/Nastran using 2D and 3D elements for different type of stress analyses,
- Analytical assumptions are used for the nodes to create a region for transition of the material properties,
- FE optimization uses Wolfram Mathematica codes for to generate Msc. Patran PCL functions, which create Msc. Nastran input for the optimization cycle,
- Manufacturing of the AGS panel use methods of resin infusion process under vacuum,
- Quality evaluation of the AGS panel use macroscopic methods to check.

2. LITERATURE REVIEW

This chapter summarizes the literature study conducted as a part of the project. Analytical approaches to grid stiffened panels, finite element approaches to grid stiffened panels, methods of grid stiffened panel manufacture and optimization of grid stiffened panels are given briefly from the historical studies. Due to the fact that the focus of the project is including almost all the steps to develop composite AGS panel, emphasis is put on all the subjects possible.

2.1 Analytical Approaches to Grid Stiffened Panels

Formerly, behavior of grid structures was understood from practical experience which searches for several standard grid lattice shapes. Recently, smearing technique has been developed for prediction of the equivalent stiffness and failure of the grid structure. Smearing of the stiffness properties of skin and the stiffener gives accurate results for the overall panel performance. This method can be applied both in-plane (membrane) and out-of-plane (bending) properties. The significant drawback of the smearing method is the lack of understanding of the local effects generated by irregularities in the grid structure pattern (Kassapoglou, 2013; Huybrechts and Tsai, 1995).

Chen and Tsai (1996) is studied on an integrated equivalent stiffness method (ESM) to model a grid structure with or without laminate skins. This method was especially applied for isogrid, orthogrid and angle grid patterns. The in-plane bending, torsion and shear of the ribs adapted to Mindlin's plate theory, and skin and rib local buckling ratios using Galerkin's method are defined for simply supported boundary condition. The results with this model give accurate values for displacements and acceptable values for strain and stress. But, like all the smearing models, local structural response or structural failure cannot be predicted when the contact area of the applied load is smaller than the size of the unit cell.

A generalized analytical model for to predict the static structural behavior without smearing the stiffness properties of rib and skin is studied by Li and Cheng (2007),

for various grid-stiffened composite structures. In this paper, analysis model is generalized for both empty bay, which means the open space between the ribs is not filled, and filled bay, which means the open space between the ribs are filled with light-weight material. Based on classical laminate theory; empty bay is assumed to be an inclusion and filled bay is introduced by stiffness distribution function. The reason of the filling the bay area with light-weight material is to protect the ribs and skin from local buckling and crippling, and to reduce the impact effect on the skin. It is concluded that lower bay density increases the interaction between the filler and the rib, when critical value reached for the bay density AGS sandwich structure behaves like pure laminated composite.

Kidane et al. (2003) studied on buckling load for cross and horizontal grid stiffened composite cylinder. Equivalent stiffness method is used for a grid stiffened composite cylindrical shell. Equivalent stiffness of the total panel is computed by superimposition of the stiffeners and the shell of the composite cylinder. Moment effect and the force analysis of the stiffener performed on the unit cell for to generalize the smearing stiffness method. Using the energy methods buckling load is calculated for particular stiffener configuration. It is concluded that the increasing the stiffener spacing results in a decrease in buckling load but after a critical point it becomes insignificant and thickness of the skin enhances the buckling resistance.

Smeared stiffener theory that includes skin-stiffener interaction effect is studied by Jaunky et al. (1996). This interaction effect computation use the stiffness of the stiffener and the skin at the stiffener region about a shift in the neutral axis at the stiffener. Therefore, the approximate stiffness added by a stiffener to the skin stiffness will be due to the plate-stiffener combination being bent about its neutral surface rather than due to the stiffener being bent about its own centroid or the plate neutral surface. Axially stiffened, orthogrid, and general grid-stiffened panels are used to find buckling loads by using the smeared stiffness combined with a Rayleigh-Ritz method. This method is more accurate than the traditional smeared stiffness approach because the skin-stiffener interaction is considered.

2.2 Finite Element Approaches to Grid Stiffened Panels

Finite element models are developed for grid stiffened composite structures due to lack of understanding of AGS buckling and dynamic behavior. Most of the cases

theories include the thick plate theory, so that thin plates can also be covered using some mathematical approaches. Different type of AGS unit cells can be taken into account efficiently by using discrete methods and in addition to that parametric studies are conducted with this flexibility to create failure types and envelopes.

Moorthy (2012) studied on cylinder with and without grid stiffened and the outcomes of the analyses are checked for the different shell thicknesses. Possible failure modes, which are elastic buckling and material failure of the medium thick composite shells under external pressure with inclusion of transverse shear deformation, are presented. It is concluded that critical buckling pressure is much higher at ring stiffened cylinder for the same lamina thickness.

FE buckling analysis of stiffened plates and shells using modified approach of shell and stiffener modeling is studied by Prusty and Satsangi (2001). Shell is modeled with an eight node iso-parametric quadratic element and stiffener is modeled with a three node curved stiffener element. Equal displacement concept is used at the junction of the shell and stiffener. FE formulation on this paper is based on the first order shear deformation theory for stiffened plates and cylindrical shells. It is concluded that substantial improvement achieved over the existing approaches of analysis of stiffened panel.

Ray and Satsangi (1999) studied on FE analysis for first ply failure of composite stiffened plates using an eight node isoparametric quadratic plate bending element and three node isoparametric beam element. The main advantage of this type of application is that there is no limitation for placing the stiffener on any direction inside the plate element.

Akl and El-Sabbagh (2008) research is about FE approach of grid stiffened plates using 2D 8-node plate element that can be modeled with stiffeners. The main purpose of this paper is to develop an efficient FE model to capture the dynamics of stiffened panel which has arbitrarily distributed stiffeners. The proposed FE element reduced number of elements (110 elements) used to model the same configuration with ANSYS conventional plate elements (7432 elements). The presented theoretical and experimental results in this paper show the accuracy of the proposed element and its flexibility to model stiffeners arbitrarily.

Huybrechts and Tsai (1995) studied on FE model to construct failure envelopes for different parameters of grid stiffened panels. Grid-specific finite element model is developed to reduce the time for analysis. The effect of the nodal offset, which is distance between the intersecting nodes made intentionally to prevent from build-up more than 2 grids, is put into the global grid structure stiffness matrix and a skin finite element, which is triangular elements, derived with offset degrees of freedom. Failure criteria are also developed to predict failure of grid structure from deflection, instability of grids (fixed ends) and material failure. It is concluded that major failure is the rib buckling for grid structures with thin ribs, adding rib directions occasionally reduce the failure strength of a grid structure, angled ribs are carrying the most of the shear loads and in many cases, nodal offsets decrease material failure loads while increasing the buckling failure load.

Cho and Kim (1999) article was about FE linear buckling analysis of grid stiffened composite plates and a hybrid element with drilling degrees of freedom, which is defined at the in-plane dimension, is proposed to satisfy the compatibility condition at the interface between skin and stiffeners. This element reduces the effect of the sensitivity of mesh distortion and matches the degrees of freedom between skins and stiffeners. The buckling analyses use stress loading and the displacement loading that is derived from the load distributions of first step. The parametric study shows that three types of buckling modes exist in isogrid and cross stiffened panel; global mode, local skin-buckling mode, and stiffener buckling mode, increase in stiffener height follows the buckling modes transition from global to local skin to stiffener and maximum load for buckling occurs at the local skin buckling mode.

FE element model of the Minotaur fairing of space vehicle which is linked to Hypersizer program is researched by Wegner et al. (2002). Hypersizer offers structural optimization using smeared-stiffener model to analyze the stability according to rib crippling, skin pocket buckling and global Euler buckling for grid stiffened structures. Afterwards, the detailed analysis conducted on the fairing with hardware attachments and the strength of the epoxy bond between the rib and the skin is analyzed as a secondary failure. It is concluded that the design of this fairing validated with a great deal of experimental data.

Post buckling behavior and the failure of AGS structures under thermal-mechanical load using FE method was done by Bai et al. (2007). Their model is based on the first

order shear theory under the assumption of Von Karman non-linear deformation. Progressive failure, buckling, large deformation and local failure modes in AGS structure is taken into account for their study. It is concluded that stiffness degradation caused by progressive failure of the stiffeners.

Meink (n.d) studied on a comparison of composite grid and composite sandwich shroud using FE modeling. He used IDEAS to run global buckling and deflection solution. FE model used in this study can only use smeared stiffener laminate for material failure and global buckling properties.

Chen and Tsai (1996) study was about FEM technique that can be adapted to the integrated equivalent stiffness model using Mindlin's theory. Exact FEM modeling, that uses the equivalent stiffness model, can obtain a refined stress analysis with high precision. SDRC I-DEAS code is used to check stresses and local buckling from FEM analysis.

Buckling of isogrid plates using FE modeling was also investigated by Lavin and Miravete (2010). FE models are developed using COMSOL Multiphysics to predict buckling modes.

2.3 Methods of Grid Stiffened Panel Manufacture

Manufacturing of unstiffened shell (with skin only), lattice cylinder (with ribs only) and grid-stiffened shell (with skin and ribs) by filament winding is explained in Buragohain and Velmurugan (2011) paper. The unstiffened composite shell is manufactured by circumferential winding. Manufacture of the grid stiffened structure followed the groove winding procedure instead of free winding, which does not need tooling, due to low quality rib results. Tooling is selected as rigid polyurethane foam machined cylindrically, instead of silicon rubber and plaster, and it is cut by rotary end-mill cutter for to open circumferential and helical grooves. A resin coat is applied on the mandrel to improve the surface finish and a thin film of polyvinyl alcohol is applied as releasing agent. Winding process controlled by the CNC filament winding machine and fiber tension is maintained for better quality. Geometrical imperfections and non-uniform skin thickness were observed in very thin walled shells. Thickness variation from crossover to rib segments distorts the cylindrical cross-sectional shape along the outer periphery.

Huybrechts et al. (n.d.) listed the proven manufacturing methods, which show the actual grid structure behavior, from the vast number of literature;

- Wet winding (the Brute Force Approach),
- Wet winding around pins by Russian researchers,
- Wet winding in hard tooling with E-Beam cure by Boeing,
- Nodal spreading by Stanford University,
- Winding into solid rubber tooling by Philips Lab,
- The hybrid tooling method by Air Force Research Laboratory (AFRL),
- Fiber placement with hybrid tooling by AFRL & Boeing,
- Fiber placement with expansion inserts by Alliant Tech Systems,
- The located expansion tooling method by AFRL & Boeing,
- The SnapSnat method by Composite Optics,
- The RIG method by Stanford University.

It is also stated a couple of automated methods to manufacture AGS structures.

Philips laboratory used solid cured silicon rubber sheets wrapped around metallic mandrels for cylindrical sections. Rib intersections have the build-up problem that also affects the continuity of the fiber. High coefficient of thermal expansion (CTE) of silicon rubber provides expansion at curing temperature of the ribs to prevent the fiber sparse areas especially near the nodes. Rib quality near these regions is significantly low without consolidation of the ribs provided by the lateral expansion by silicon rubber. The drawbacks of expansion block method are the lack of control over the compaction caused by silicon rubber, warping of tooling due to high CTE, high thermal/mechanical stresses in the finished part and difficulty in producing more complex shapes to have proper groove alignment.

Hybrid tooling method tries solving these problems, which is explained in previous paragraph, with addition of expansion tooling inserts in a thermally stable base tool. This method provides precise control of lateral rib compaction and it can be applied to complex shapes without the problems of groove alignment or helix angle of rib.

This study also captures manufacture of payload shroud using hybrid tooling method with 5-Axis filament winding machine. Three parts are used to build this method are stainless steel base mandrel, base tooling material and silicon rubber expansion inserts (Huybrechts and Meink, n.d.).

Huybrechts et al. (2002) mentioned about the problem of almost all manufacturing methods of AGS structures that is nodal build-up. This build-up nodal points cause loss of strength, stiffness and modeling accuracy. Two stable tooling concepts are explained:

- Hybrid tooling has base tool and silicon rubber expansion tool. The base tool is cut to make grooves for rib directions and an expansion block, which is silicon rubber, is put into these grooves to provide consolidation for the woven fibers at the high temperature curing phase.
- Expansion block tooling has advantage to apply for different rib geometries. It has a base tool, which is stiff and stable, and expansion blocks with high coefficient of thermal expansion (CTE). Lateral compaction for the ribs is provided by expansion blocks.

Kim (2000) studied on fabrication of thin composite isogrid stiffened panel. Nodal offset is used for to reduce build-up effect on the manufacturing and the empty space due to nodal offset is filled with the resin. The advantage of filling with resin is stronger skin to rib bonding and possible mounting points such as hinges and electronic equipment.

In fabrication, metal isogrid tool used to cast silicon rubber mold and steel base plate is covered with borders to constrain the rubber from expanding at high temperatures. All the fibers laid into grooves between silicon rubber and steel caul plate used at the top of the skin to obtain good compaction.

Dutta (1998) summarized manufacturing methods of composite grids. The major considerations about manufacturing of composite grid structures; all ribs has to be unidirectional, rib cross-section must be well defined and nodes must have continuous fibers.

Composite grids are initially manufactured based on traditional slotted joint manufacturing system at Stanford University. The composite grids, which will be slotted afterwards, are manufactured using pultruded thin unidirectional sections. The disadvantages of this process include, cost of machining slots, difficulty on assemblage of ribs having multiple slotted ribs, loss of stiffness and strength due to machined slots and imperfect fit at slotted joints, and limited grid configuration as square or rectangular. The upper limit of the fiber volume fraction in the ribs is

controlled by the node sections, generally 60 percent and 30 percent at the ribs. Application of node offset method can increase the fiber fraction in the ribs. The fiber fraction can be increased further by designing nodes wider and it will reduce the thickness of interlacing layers.

Direct crossover interlaced joints method use the wet winding process and at the node section fibers are continuous and crossing over each other. Fibers at the joints were consolidated periodically by hand to maximize compaction and fiber volume. The silicon rubber mold provided good compaction and consolidation during curing of the product.

Stanford Pin Enhanced Geometry (PEG) Process is a modified process of direct crossover interlaced joints, which has resin pool, fiber warping, and wrinkle problem. In this method central pin node without any lead angle and a pattern with 1.3 degree lead angle to smoothen the rib-node transition are used. Alternating placement and laminated lay-up pattern are used but this does not provide reduction on the node thickness to rib thickness and the single pin in the middle disturbs the fibers and causes dry zones. A follow-up modification of four pin instead of one pin used to have better specimen. In later attempts, fibers are forced to conform properly during cure cycle but resin pool, fiber undulations, wrinkles remained and resin poor regions in the nodes appeared.

Stanford Tooling-Reinforced Interlaced Grid (TRIG) Process is a process developed for the flat orthogrid. This method changes conventional concept of tooling by using it as integral part of the finished structure. Similar mold blocks, which are used for PEG method, are also used for TRIG. Tooling blocks are placed on the wooden base plate with guiding lines and vacuum bag film for easy separation. Tooling blocks are filament-wound composite tube segments with outer cross sectional geometry becoming the grid channel geometry. Nails are positioned at the ends of each channel to provide fiber tension and continuity. Wetted fibers are wound into channels between tooling blocks and then waited until resin is cured. The disadvantage of TRIG involves direct crossover in the nodes, the open inspection of molded grids is not possible, and the integrated tooling increases weight.

A demonstration of current technology revealed that composite grids generally suffer from manufacturing problems of low density interlacing, no fiber tension, and excessively thick nodes with direct roving crossovers (Dutta, 1998).

2.4 Optimization of Grid Stiffened Panels

Optimization of grid stiffened panels is mandatory to find the best configuration inside the design space. Design space includes all kind of failure types and dimensioning, thus expectation is to search a point which is converging at the optimum. Thus optimization models are designed and run with intrinsic algorithms as it is referenced in this section.

Chen and Tsai (1996) is studied on the optimization of the composite grid structures. Their design space include grids with or without skins, orthotropic grids that consist 0, 90, and $\pm\theta^\circ$ directional ribs, rectangular ribs with equal height, symmetric skin laminate lay-up. Loading conditions are hygrothermal and multiple mechanical. The failure modes are material failure and the local buckling of skins and ribs. Direct search method, which is a solution method for the problems that does not require any information about the gradient of the objective function, is selected.

Optimization of the curvilinear (alignment) stiffeners on different loading conditions is studied by Mulani et al. (2011). Gradient based and/or global optimizations are developed to minimize the mass, and constrains are buckling, Von Misses stress, and crippling or local failure of the stiffener. Design variables are orientation, the shape of the stiffeners, the spacing between the stiffeners, stiffeners thickness and height, and thickness of the plate. An optimization framework is created using MD-PATRAN (Geometry Modeling), MD-NASTRAN (FEM Analysis), VisualDOC (External Optimizer) and MATLAB (Central Processor) to optimize the stiffened panels using grid-stiffening concept and the curvilinear stiffeners.

Wodesenbet (2003) used equivalent stiffness of the shell/stiffener to optimize the grid stiffened composite panels. Parametric study is performed on the different design variables, which are shell thickness, shell winding angle, longitudinal modulus and stiffeners orientation angle and their effect on buckling load is presented. Increase in skin thickness results in higher buckling resistance of stiffened structure. The effect of stiffener orientation angle and longitudinal modulus increase also results in higher buckling resistance of the stiffened cylinder structure.

Akl et al. (2008) studied on optimization of iso-grid stiffened plate for the static and dynamic characteristic of these plates/stiffeners assemblies. Static part of optimization tries to maximize critical buckling load of the iso-grid plate, while

dynamic part of optimization tries to maximize multiple natural frequencies of the stiffened plate. A FE model is developed for Mindlin plates with arbitrary stiffeners and this model is used as a basis for optimization of critical buckling load and natural frequencies of stiffened plate. The plate is modeled using an 8-node isoparametric element, which is formulated using the first-order shear deformation theory and the stiffeners are modeled using a 3-node element based on the Timoshenko beam theory. Using this approach, stiffeners located arbitrary along a plate structure can be easily modeled without the need to change the ground mesh of the plate model. The analysis to maximize the first six critical buckling loads resulted in optimum stiffener inclination angle of 35° .

Phillips and Gürdal (1990) research was about optimum design of the geodesic panels (diagonal and cross) and the longitudinally stiffened panels to achieve minimum weight. The design variables are skin thickness (quasi-isotropic laminate), stiffener height, and stiffener thickness and increasing number of stiffened cells used for panel configuration. Uniaxial compression, pure shear and combined compression-shear loads are applied. PANSYS is used to seek minimum-weight wing rib designs subject to constraints on both buckling resistance and material strength. It is concluded that under compression loading diagonal and cross geodesically stiffened panels are lighter than the longitudinally stiffened panel and minimum mass achieved at higher number of stiffened cells, under shear loading it gives almost similar results and cross stiffened panel appears to be most feasible design and under compression-shear loading.

3. THEORETICAL MODEL AND FUNDAMENTAL EQUATIONS

Theoretical model is derived from the classical laminate theory in this chapter. Intersecting nodes material properties and failure strength is defined in detail. Extensional, coupling, and bending stiffness matrices for composite parts are calculated. Additionally, failure mechanisms, i.e. stiffener crippling, Euler buckling, is studied for to implement the analytical equations into optimization cycle.

3.1 Classical Laminate Theory

A lamina is a thin layer of a composite structure and a laminate is formed by stacking a number of laminae. Mechanical analysis of a lamina follows the way of computation for to reach properties of the laminate. A lamina is not an isotropic homogenous material. The lamina consists of two parts; first is isotropic homogenous fibers and second is an isotropic homogeneous matrix. The different stiffness properties of points in the lamina originate from its location, which is in the fiber, the matrix, or the fiber-matrix interface. The difficulty of mechanical modeling of the lamina leads to macro-mechanical analysis based on average properties and consideration of homogeneous laminate. However, mechanical behavior of the lamina is still different than homogeneous isotropic material (Kaw, 2006).

The unidirectional fiber-reinforced composite is treated as a two-phase material, with the axis of the reinforcing fibers aligned parallel and packed randomly in the plane transverse to the fiber axis. The governing constitutive equation of this composite is the generalized Hooke's law. The material coefficients of this equation are expressed as functions of the material and geometric parameters of the constituent materials.

The laminated composite is assembled by bonding together unidirectional layers of identical mechanical properties, with adjacent layers orthogonal to each other (cross-ply) or oriented symmetrically with respect to an arbitrary reference axis (angle-ply). The governing constitutive equation is the relation between the in-plane stress and moment and the in-plane strain and curvature. The material coefficients of this

equation are expressed as functions of the properties of the unidirectional composite and lamination parameters (Tsai, n.d.).

The most general stress-strain relationship is given as equation (3.1) for three-dimensional body in a 1-2-3 orthogonal Cartesian coordinate system.

$$\begin{bmatrix} \sigma_1 \\ \sigma_2 \\ \sigma_3 \\ \tau_{23} \\ \tau_{31} \\ \tau_{12} \end{bmatrix} = \begin{bmatrix} C_{11} & C_{12} & C_{13} & C_{14} & C_{15} & C_{16} \\ C_{21} & C_{22} & C_{23} & C_{24} & C_{25} & C_{26} \\ C_{31} & C_{32} & C_{33} & C_{34} & C_{35} & C_{36} \\ C_{41} & C_{42} & C_{43} & C_{44} & C_{45} & C_{46} \\ C_{51} & C_{52} & C_{53} & C_{54} & C_{55} & C_{56} \\ C_{61} & C_{62} & C_{63} & C_{64} & C_{65} & C_{66} \end{bmatrix} \begin{bmatrix} \epsilon_1 \\ \epsilon_2 \\ \epsilon_3 \\ \gamma_{23} \\ \gamma_{31} \\ \gamma_{12} \end{bmatrix} \quad (3.1)$$

and in equation (3.2) the inverse of it gives the compliance matrix [S].

$$\begin{bmatrix} \epsilon_1 \\ \epsilon_2 \\ \epsilon_3 \\ \gamma_{23} \\ \gamma_{31} \\ \gamma_{12} \end{bmatrix} = \begin{bmatrix} S_{11} & S_{12} & S_{13} & S_{14} & S_{15} & S_{16} \\ S_{21} & S_{22} & S_{23} & S_{24} & S_{25} & S_{26} \\ S_{31} & S_{32} & S_{33} & S_{34} & S_{35} & S_{36} \\ S_{41} & S_{42} & S_{43} & S_{44} & S_{45} & S_{46} \\ S_{51} & S_{52} & S_{53} & S_{54} & S_{55} & S_{56} \\ S_{61} & S_{62} & S_{63} & S_{64} & S_{65} & S_{66} \end{bmatrix} \begin{bmatrix} \sigma_1 \\ \sigma_2 \\ \sigma_3 \\ \tau_{23} \\ \tau_{31} \\ \tau_{12} \end{bmatrix} \quad (3.2)$$

Compliance matrix is the inverse of the stiffness matrix given in equation (3.3).

$$[S] = [C]^{-1} \quad (3.3)$$

This 6x6 [C] matrix is called the stiffness matrix that has 36 constants. Due to the symmetry of the stiffness matrix [C], number of constants reduces to 21. Anisotropic material has 21 independent elastic constants at a point, and stress-strain relationship is generated with decision of these constants.

The nine engineering constants (elastic moduli, Poisson ratios, and shear moduli) are calculated from the composite flexibility matrix [S] as equation (3.4).

$$\begin{aligned} E_i &= \frac{1}{S_{ii}} & i &= 1,2,3 \\ \nu_{ij} &= -S_{ij}E_i & ij &= 12, 23, 31 \\ G_{ij} &= \frac{1}{S_{(i+3)(i+3)}} & ij &= 12, 23, 31 \end{aligned} \quad (3.4)$$

Materials with three perpendicular planes of symmetry called orthotropic material has stiffness matrix as given in equation (3.5).

$$[C] = \begin{bmatrix} C_{11} & C_{12} & C_{13} & 0 & 0 & 0 \\ C_{12} & C_{22} & C_{23} & 0 & 0 & 0 \\ C_{13} & C_{23} & C_{33} & 0 & 0 & 0 \\ 0 & 0 & 0 & C_{44} & 0 & 0 \\ 0 & 0 & 0 & 0 & C_{55} & 0 \\ 0 & 0 & 0 & 0 & 0 & C_{66} \end{bmatrix} \quad (3.5)$$

Three plane of symmetry gives,

$$C_{16} = 0, C_{26} = 0, C_{36} = 0, C_{46} = 0, C_{56} = 0 \quad (3.5a)$$

$$C_{14} = 0, C_{24} = 0, C_{34} = 0, C_{15} = 0, C_{25} = 0, C_{35} = 0, C_{45} = 0 \quad (3.5b)$$

Three mutually perpendicular planes of material symmetry also provide three mutually perpendicular planes of elastic symmetry.

A unidirectional lamina can be considered as thin plate, therefore there are no out of plane loads. This condition is called plane stress, which upper and lower surface of the plate is free from external loads ($\sigma_3=0, \tau_{31}=0, \tau_{23}=0$). These three stresses vary little from top to bottom surface, thus it is assumed to be zero within plate. This assumption reduces the three dimensional case to two dimensional stress-strain equation. An orthotropic plane stress problem can be written as equation (3.6).

$$\begin{bmatrix} \epsilon_1 \\ \epsilon_2 \\ \gamma_{12} \end{bmatrix} = \begin{bmatrix} S_{11} & S_{12} & 0 \\ S_{12} & S_{22} & 0 \\ 0 & 0 & S_{66} \end{bmatrix} \begin{bmatrix} \sigma_1 \\ \sigma_2 \\ \tau_{12} \end{bmatrix} \quad (3.6)$$

where axis-1 shows the parallel direction to the fibers and axis-2 perpendicular direction to the fibers. Inverting the equation gives stress-strain relationship as shown in equation (3.7).

$$\begin{bmatrix} \sigma_1 \\ \sigma_2 \\ \tau_{12} \end{bmatrix} = \begin{bmatrix} Q_{11} & Q_{12} & 0 \\ Q_{12} & Q_{22} & 0 \\ 0 & 0 & Q_{66} \end{bmatrix} \begin{bmatrix} \epsilon_1 \\ \epsilon_2 \\ \gamma_{12} \end{bmatrix} \quad (3.7)$$

where Q_{ij} are the reduced stiffness coefficients, which are related to compliance coefficient.

$$Q_{11} = \frac{S_{22}}{S_{11}S_{22}-S_{12}^2}, \quad Q_{12} = \frac{S_{12}}{S_{11}S_{22}-S_{12}^2} \quad (3.7a)$$

$$Q_{22} = \frac{S_{11}}{S_{11}S_{22}-S_{12}^2}, \quad Q_{66} = \frac{1}{S_{66}}$$

The above equations give the properties for unidirectional fibers but most of the time some laminae are placed at an angle for to provide higher stiffness and strength properties in the transverse direction. Angle lamina can be defined in its own local coordinate system or material coordinate system (1-2 coordinate system), and then the properties can be translated into global coordinate system (x-y coordinate system). The angle between two coordinate systems is denoted by an angle θ .

Stress-strain relationship for angle lamina uses transformed reduced stiffness matrix $[\bar{Q}]$, which is applied as equation (3.8).

$$\begin{bmatrix} \sigma_1 \\ \sigma_2 \\ \tau_{12} \end{bmatrix} = \begin{bmatrix} \bar{Q}_{11} & \bar{Q}_{12} & \bar{Q}_{16} \\ \bar{Q}_{12} & \bar{Q}_{22} & \bar{Q}_{26} \\ \bar{Q}_{16} & \bar{Q}_{26} & \bar{Q}_{66} \end{bmatrix} \begin{bmatrix} \varepsilon_1 \\ \varepsilon_2 \\ \gamma_{12} \end{bmatrix} \quad (3.8)$$

whereas equation (3.9) to (3.14),

$$\bar{Q}_{11} = Q_{11}c^4 + Q_{22}s^4 + 2(Q_{12} + 2Q_{66})s^2c^2 \quad (3.9)$$

$$\bar{Q}_{12} = (Q_{11} + Q_{22} - 4Q_{66})s^2c^2 + Q_{12}(c^4 + s^4) \quad (3.10)$$

$$\bar{Q}_{22} = Q_{11}s^4 + Q_{22}c^4 + 2(Q_{12} + 2Q_{66})s^2c^2 \quad (3.11)$$

$$\bar{Q}_{16} = (Q_{11} - Q_{12} - 2Q_{66})c^3s - (Q_{22} - Q_{12} - 2Q_{66})s^3c \quad (3.12)$$

$$\bar{Q}_{26} = (Q_{11} - Q_{12} - 2Q_{66})s^3c - (Q_{22} - Q_{12} - 2Q_{66})c^3s \quad (3.13)$$

$$\bar{Q}_{66} = (Q_{11} + Q_{22} - 2Q_{12} - 2Q_{66})s^2c^2 + Q_{66}(s^4 + c^4) \quad (3.14)$$

where $s = \sin \theta$, $c = \cos \theta$. They are functions of the four stiffness elements, Q_{11} , Q_{12} , Q_{22} , and Q_{66} , and the angle of the lamina, θ .

Above equations are developed for a single lamina. Real structure consists of more than one lamina bonded together at different angles for given loading and stiffness requirements. Classical lamination theory is used to develop for a laminate under in-plane loads such as shear and axial forces, and bending and twisting. The following assumptions are used in the classical lamination theory:

- Each lamina is orthotropic.
- Each lamina is homogeneous.

- A line straight and perpendicular to the middle surface remains straight and perpendicular to the middle surface during deformation ($\gamma_{xz}=\gamma_{yz}=0$).
- The laminate is thin and is loaded only in its plane (plane stress) ($\sigma_z=\tau_{xz}=\tau_{yz}=0$).
- Displacements are continuous and small throughout the laminate ($|u|, |v|, |w| \ll |h|$), where h is the laminate thickness.
- Each lamina is elastic.
- No slip occurs between the lamina interfaces.

A laminate made of n plies can be considered with thickness of each ply t_k . Then the thickness of the laminate h is given in equation (3.15).

$$h = \sum_{k=1}^n t_k \quad (3.15)$$

Location of the mid-plane is $h/2$ from the top and the bottom surface of the laminate. The z -coordinate of each ply k surface is given below,

Ply 1

Top surface $h_0 = -\frac{h}{2}$ (3.15a)

Bottom surface $h_1 = -\frac{h}{2} + t_1$

Ply k : ($k=2, 3 \dots n-2, n-1$)

Top surface $h_{k-1} = -\frac{h}{2} + \sum_{i=1}^{k-1} t_i$ (3.15b)

Bottom surface $h_k = -\frac{h}{2} + \sum_{i=1}^{k-1} t_i$

Ply n

Top surface $h_{n-1} = \frac{h}{2} - t_n$ (3.15c)

Bottom surface $h_n = \frac{h}{2}$

Then, global stresses in each lamina can be integrated, and the resultant forces and the resultant moments per unit length in the x-y plane through the laminate thickness can be found. The resultant force and moments can be written in terms of mid-plane strains and curvatures and also the transformed reduced stiffness matrix, $[\bar{Q}]$, can be combined into equation. Then, the $[A]$, $[B]$, $[D]$ matrices, which are called the extensional, coupling, and bending stiffness matrices respectively, can be written as equation (3.16) to (3.18).

$$A_{ij} = \sum_{k=1}^n [(\bar{Q}_{ij})]_k (h_k - h_{k-1}), \quad i = 1,2,6; \quad j = 1,2,6 \quad (3.16)$$

$$B_{ij} = \frac{1}{2} \sum_{k=1}^n [(\bar{Q}_{ij})]_k (h_k^2 - h_{k-1}^2), \quad i = 1,2,6; \quad j = 1,2,6 \quad (3.17)$$

$$D_{ij} = \frac{1}{3} \sum_{k=1}^n [(\bar{Q}_{ij})]_k (h_k^3 - h_{k-1}^3), \quad i = 1,2,6; \quad j = 1,2,6 \quad (3.18)$$

The forces applied to a small part of the laminate, can be described by 6 components in classical shell theory, 3 in-plane forces and 3 moments. Generalized constitutive equation (3.19) for any laminate have form.

$$\begin{bmatrix} N_x \\ N_y \\ N_{xy} \\ M_x \\ M_y \\ M_{xy} \end{bmatrix} = \begin{bmatrix} A_{11} & A_{12} & A_{16} & B_{11} & B_{12} & B_{16} \\ A_{12} & A_{22} & A_{26} & B_{12} & B_{22} & B_{26} \\ A_{16} & A_{26} & A_{66} & B_{16} & B_{26} & B_{66} \\ B_{11} & B_{12} & B_{16} & D_{11} & D_{12} & D_{16} \\ B_{12} & B_{22} & B_{26} & D_{12} & D_{22} & D_{26} \\ B_{16} & B_{26} & B_{66} & D_{16} & D_{26} & D_{66} \end{bmatrix} \begin{bmatrix} \epsilon_x^0 \\ \epsilon_y^0 \\ \gamma_{xy}^0 \\ \kappa_x \\ \kappa_y \\ \kappa_{xy} \end{bmatrix} \quad (3.19)$$

where,

N_x, N_y = normal force per unit length

N_{xy} = shear force per unit length

M_x, M_y = bending moments per unit length

M_{xy} = twisting moment per unit length

(3.19a)

Symmetric laminates have no membrane-stretching coupling behavior that makes [B] coupling matrix zero. Denoting the inverse of the [A] matrix by [a] and the inverse of the [D] matrix by equation (3.20) become for symmetric laminate.

$$\begin{bmatrix} \varepsilon_x^0 \\ \varepsilon_y^0 \\ \gamma_{xy}^0 \\ \kappa_x \\ \kappa_y \\ \kappa_{xy} \end{bmatrix} = \begin{bmatrix} a_{11} & a_{12} & a_{16} & 0 & 0 & 0 \\ a_{12} & a_{22} & a_{26} & 0 & 0 & 0 \\ a_{16} & a_{26} & a_{66} & 0 & 0 & 0 \\ 0 & 0 & 0 & d_{11} & d_{12} & d_{16} \\ 0 & 0 & 0 & d_{12} & d_{22} & d_{26} \\ 0 & 0 & 0 & d_{16} & d_{26} & d_{66} \end{bmatrix} \begin{bmatrix} N_x \\ N_y \\ N_{xy} \\ M_x \\ M_y \\ M_{xy} \end{bmatrix} \quad (3.20)$$

3.1.1 Material property of intersecting nodes

Stiffener properties of the AGS structure are not constant along its length due to nodal build-ups. Total number of fibers increases two or more than two times at node points based on nodal offset decision of the design, thus fiber volume fraction increases up to 80 percent. Moreover, fibers that are crossing over each other at nodes have different material axis direction depending on the pattern of the AGS application. These nodal section characteristics of the AGS panel need to be defined in one ply, which has to provide continuity along all the stiffeners (Kassapoglou, 2013).

According to the angles of intersecting grids, equivalent symmetric lay-ups are used to include the different material axes into one by using in-plane properties taken from Equation. Equations are used to develop effective in-plane properties as equations (3.21) to (3.25).

$$E_x = \frac{1}{ha_{11}} \quad (3.21)$$

$$E_y = \frac{1}{ha_{22}} \quad (3.22)$$

$$G_{xy} = \frac{1}{ha_{66}} \quad (3.23)$$

$$\nu_{xy} = -\frac{a_{12}}{a_{11}} \quad (3.24)$$

$$\vartheta_{yx} = -\frac{a_{12}}{a_{22}} \quad (3.25)$$

and orthotropic 3D symmetry relations comply with equations (3.26) and (3.27).

$$\begin{aligned} -\frac{\vartheta_{yx}}{E_2} &= -\frac{\vartheta_{xy}}{E_1} \\ -\frac{\vartheta_{zx}}{E_3} &= -\frac{\vartheta_{xz}}{E_1} \end{aligned} \quad (3.26)$$

$$-\frac{\vartheta_{zy}}{E_3} = -\frac{\vartheta_{yz}}{E_2}$$

$$\vartheta_{xz}\vartheta_{yx}\vartheta_{zy} = \vartheta_{xy}\vartheta_{yz}\vartheta_{zx} \quad (3.27)$$

The calculated properties of the transition sections are given in Table 3.1. These properties are derived from the UD and angle ply symmetric laminates. Efficient properties are then used for single ply and transitions region concept is set up.

The concept of increasing width of the stiffeners is used near the nodal areas of the AGS panel and this section of the stiffeners is named as transition regions. Transition region is starting from 10 to 15 mm before the grid nodes due to interruption of continuity. Then meaning of continuity for this application is the change of the fiber angle along its path due to crossover mechanism at grid nodes. Another important reason for using transition region concept is to reduce the fiber fraction by increasing the area of the grid nodes and near these regions.

As can be seen from the Table 3.2, transition starts from 22% and then it follows the increasing order 43%, 64%, and 78%. When transition percentage increases up to 100% of the material properties of intersecting node is reached.

3.2 Material Failure Analysis

The strength of the laminate is related to the strength of each individual lamina. There are various theories to check failure of a laminate. The failure theories are

based on stresses in the material or local axes due to orthotropic characteristic of the composite structures. A unidirectional (UD) lamina has two directions for its own material axes, thus there are four normal strength parameters existing for tension case and compression case. The fifth strength parameter, which can be positive or negative, is the shear strength of UD lamina. The sign of the shear stress has no effect on the strength of the UD lamina but for angle lamina sign of shear stress affect the strength properties. The five strength parameters are given for UD lamina as follow.

$$\begin{aligned}
(\sigma_1^T)_{\text{ult}} &= \text{Ultimate longitudinal tensile strength (direction 1)} \\
(\sigma_1^C)_{\text{ult}} &= \text{Ultimate longitudinal compressive strength (direction 1)} \\
(\sigma_2^T)_{\text{ult}} &= \text{Ultimate transverse tensile strength (direction 2)} \\
(\sigma_2^C)_{\text{ult}} &= \text{Ultimate transverse compressive strength (direction 2)} \\
(\tau_{12})_{\text{ult}} &= \text{Ultimate in-plane shear strength (plane 12)}
\end{aligned} \tag{3.28a}$$

For an angle lamina, first stresses in the local axes are found and then these parameters are compared to local stresses to find whether lamina has failed (Kaw, 2006).

Maximum Stress Failure Theory is used in FE optimization for material failure. Failure is predicted in a lamina by comparing the normal and the shear stresses in the local axes, and corresponding ultimate strengths of the unidirectional lamina. Lamina is considered to be failed if,

$$\begin{aligned}
-(\sigma_1^C)_{\text{ult}} &< \sigma_1 < (\sigma_1^T)_{\text{ult}} \text{ , or} \\
-(\sigma_2^C)_{\text{ult}} &< \sigma_2 < (\sigma_2^T)_{\text{ult}} \text{ , or} \\
-(\tau_{12})_{\text{ult}} &< \tau_{12} < (\tau_{12})_{\text{ult}}
\end{aligned} \tag{3.28b}$$

is violated. Here is negative sign is added to indicate compressive stresses. All the components are compared with corresponding strengths, thus there is no interaction with others.

Failure strength of CFRP is calculated using maximum stress failure theory for UD and intersecting nodes given in Table 3.3.

3.3 Instability of Stiffeners

Design of the AGS structure takes different buckling conditions into consideration as distinct cases. Two of them, which are rib crippling and column buckling, are defined by analytical and semi-empirical formulations. Each mode is assumed to be independent in a buckling resistant design (Rehfield and Deo, 1978).

Table 3.3: Failure strength of intersecting nodes (MPa).

Type	σ_1^C	σ_1^T	σ_2^C	σ_2^T	τ_{12}
UD					
0°	1400	1700	310	89.5	120
Fabric*					
0-35°	283	212	250	92	102
0-55°	308	156	253	101	95
0-70°	348	132	286	111	103
0-90°	350	120	350	120	120
35-90°	253	101	308	156	103

3.3.1 Rib crippling

Crippling is a local behavior and occurs on rib sections which are smaller than full rib length. When crippling starts on any of the stiffeners, load carrying capacity of this stiffener reduces until collapse of the crippling area. Local crippling of the ribs for compressed AGS panel does not result in total collapse of the structure.

A semi-empirical approach is used for crippling strength associated with the b/t ratio where b is height and t is width. The design equation is given as equation (3.29).

$$\sigma_{crip} = \frac{1.63}{\left(\frac{b}{t}\right)^{0.717}} \sigma_c^u \quad (3.29)$$

where σ_c^u is the ultimate compression strength of the stiffener. Although it is mentioned that use of this formulation is limited for laminates with at least 25% 0° plies and 25% 45° plies, optimization of AGS panel that is conducted in this study uses this formulation due to its simplicity and conservative nature (Kassapoglou, 2013).

3.3.2 Column buckling

Column buckling load of stiffeners can be computed from the Euler buckling analysis of beams. The difference of column buckling from crippling is that stiffener buckles at full length and it results in total collapse of stiffener between two nodes. Although substantial build-up of material at the nodes and effective increase in rib with near nodes makes boundary conditions equivalent to full clamping, the pinned end boundary is taken as the buckling case to keep conservative result. The famous equation of column buckling of pinned end beam is given as equation (3.30).

$$P_{cr} = \frac{\pi^2 E_x I}{L^2} \quad (3.30)$$

where E_x is the longitudinal direction of global axis, I is the moment of inertia and L is the length.

4. FINITE ELEMENT ANALYSIS OF FUSELAGE

This chapter elaborates on FE analysis of the composite fuselage with and without frames. 3 different models are studied for the fuselage section, fuselage without frames, fuselage with frames modeled as beam elements, fuselage with frames modeled as quad shell elements.

4.1 Modeling

A fuselage panel is modeled to find the effect of frames on the composite skin stress distribution. Different types of modelling techniques used for this analysis. Loading cases is chosen to be pressure applied inside of the composite skin. In general, fuselage is pressurized for passenger comfort. A monocoque frame, meaning external skin supports some or most of the loads, is modeled to compare how stresses are changing on pressurized loading condition. Typical loads acting on the fuselage frame are:

- Distributed load due to inside pressure,
- Concentrated forces,
- Bending moments from wings,
- Distributed shear load to balance shear forces.

The fuselage has members perpendicular to the skin, that support it and help keep its shape. These supports are called frames. Circumferential frames maintain the fuselage shape and redistribute loads into the skin. Frames give the fuselage its cross-sectional shape and prevent it from buckling, when it is subjected to bending loads. The structural strength and stiffness of the fuselage must be high enough to withstand these loads. At the same time, the structural weight must be kept to a minimum. Fuselage FE model in Figure 4.1 which internal pressure applied is studied, afterwards it can be added to other results using superposition principle if needed. Radius of the fuselage is set 2 meter and the spacing between the frames is set to 550 mm.

Figure 4.1: Fuselage FE model and cross section.

3 different models are studied for the fuselage section:

- Fuselage without frames,
- Fuselage with frames modeled as beam elements,
- Fuselage with frames modeled as quad shell elements.

MSC Nastran provides a property definition specifically for performing composite analysis. The material properties and orientation are specified by user for each of the layers and MSC Nastran produces the equivalent PSHELL and MAT8 entries. Additional stress and strain output is generated for each layer and between the layers.

Circular composite fuselage without frames, which is quasi isotropic, is modeled with quad shell elements. Quasi-isotropic laminates exhibit isotropic (that is, independent of direction) in-plane response but are not restricted to isotropic out-of-plane (bending) response. PCOMP card is used to generate quasi isotropic laminate sequence for skin (Figure 4.2) in all cases ($[0\ 0\ 60\ 60\ -60\ -60]_s$), which exhibits an isotropic in-plane material behavior.

The MAT8 card in Nastran is used to define a two-dimensional orthotropic stress-strain relationship for fuselage material. The MAT8 entry can only be used with the plate and shell elements and it defines the in-plane stress-strain relationship.

Figure 4.2: Quasi-isotropic laminate sequences for skin.

2D model of the fuselage section is meshed with CQUAD4 elements. This quadrilateral element type is preferred over the triangular element CTRIA3. When composite AGS panel, which will be explained in next chapter, is modeled with combination of CQUAD4 and CTRIA3 elements, it has been seen that CTRIA3 elements are excessively stiff. The stress results that are taken from CTRIA3 give inaccurate results when it is compared to full CQUAD4 model. Thus, it should be stated that these types of triangular elements should only be used when necessary for geometric or topological reasons, but it has to be avoided in locations where the membrane stresses are changing rapidly, for example, near the region of nodes, where two or more ribs intersecting each other.

4.2 Boundary Conditions and Loading

A pressurized circular fuselage with and without frames is modeled using PATRAN and both of the models are solved by NASTRAN which uses FE methods. The main objective is to understand the effect of the frames on stress distribution for a pressurized composite fuselage which carries a portion of the pressure loading. Pressure applied inside of the fuselage is 0.1 MPa which is about equal to atmospheric pressure on Earth at sea level, and since 1982 the IUPAC has

recommended that the standard for atmospheric pressure should be harmonized to 100,000 Pa = 1 bar.

Two boundary conditions (Figure 4.3) are used to model the fuselage:

- The first is symmetric boundary condition (T1, R2, R3), which is used to model only half of the panel on radial direction,
- The second is the simply supported (T1, T2, T3) boundary which is used to model z-direction of the cylindrical axis.

To constraint the model flying in any other degrees of freedom, one node which is far from the interest region is fixed at all degrees of freedom (T1-2-3, R1-2-3).

Figure 4.3: Symmetry boundary conditions for fuselage.

Circular composite fuselages with frames are modeled in two different ways. The first model is built by quad elements for the skin of the fuselage and frames are modeled with beam element. This model assumes that frames are isotropic but they have the same in-plane property as the effective in-plane composite frame modulus. The second way of application uses all quad elements for skin and the frames. This way of application uses duplicate elements that is connected the same nodes but with different lay-up sequences for skin and the frames. Quad element offset is applied for frames to take into account the stiffness property into the shared nodes.

4.3 Comparison

3 different models for the fuselage section are solved using linear static (SOL101) analysis option by Nastran. It is important to note that the output forces and moments generated by the shell elements are forces per unit length. A common error for new users is to assume that the force shown in the output is the total force acting on the element but it does not. It is the force per unit length. Total forces and moments are output by the line and solid elements.

Total displacement plots are given in Figure 4.4.

Figure 4.4: Comparison of displacement sum (mm).

Displacement sums are given in Figure 4.4 shows the frame on resultant translation. Comparison shows that the effect of the frame on the resultant displacement is mostly local. The maximum displacement away from the boundary changes %5.6. The difference between the beam and quad shell is that shell element shows the displacement values as separate element on the Z beam. Beam element is stiffer than quad shell as %1.5 difference on the displacement values.

Stress plots are taken as from the element centroids. Components of forces, moments, and element stresses are always output in the element coordinate system. By default, the element forces, stresses, and strains are generated for the centroid of the CQUAD4. The most critical stress values are in circumferential direction (Figure

4.5). Radial and axial directions that are defined in separate coordinate system, thus element stress outputs transformed properly to cylindrical coordinate system. Circumferential stress increase near region of the frames, and fuselage with shell frames has higher stress value than fuselage with beam frames. Frame structure affects the skin stress distribution locally. Stresses in circumferential direction decreases around %70, for axial direction it reduces up to %50 for fuselage with shell frame.

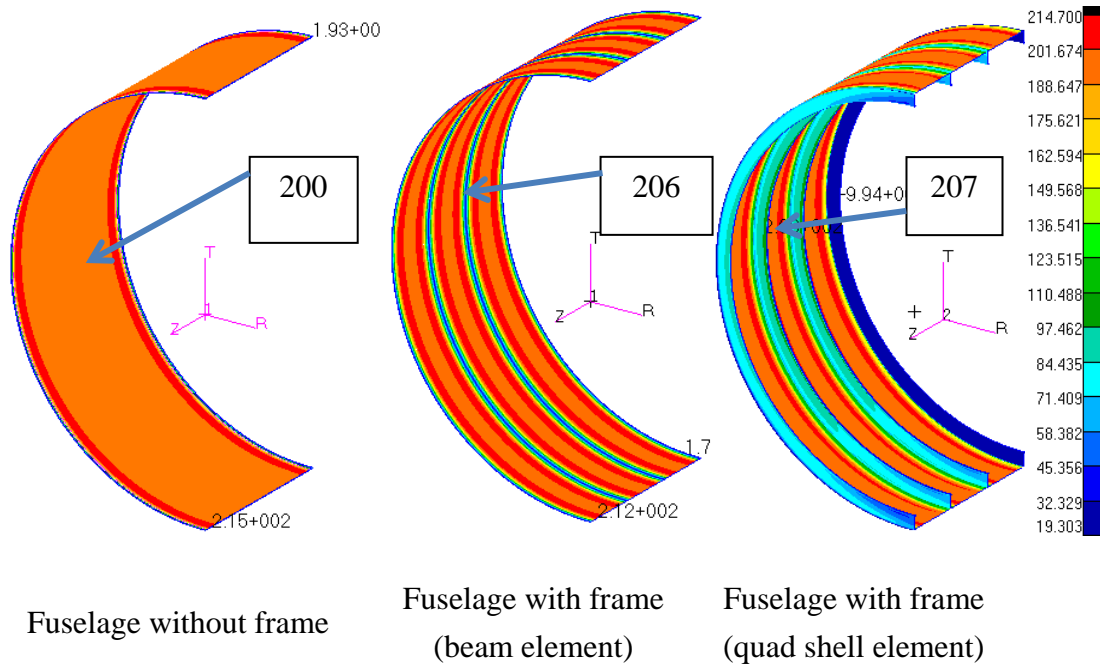

Figure 4.5: Comparison of circumferential shell forces (N/mm).

Comparison of the maximum and minimum shell forces are given in Table 4.1. It is clear that the effect of the frame on local level is significant. In global structure the change in the stress distribution will aid to preserve the shape of the fuselage. Although maximum stresses are close for all the FE models, minimum stresses decrease for both axial and circumferential direction up to %70, which increases the safety in case of failure.

Table 4.1 Comparison of shell forces (N/mm)

Configuration	Shell Forces (N/mm)					
	Circumferential (Y)		Axial (Z)		Shear (YZ)	
	Max.	Min.	Max.	Min.	Max.	Min.
Fuselage skin	200	200	61	61	0	0
Fuselage beam	206	54.6	56	56	0	0
Fuselage shell	207	69.4	56	27.7	0	0

5. FINITE ELEMENT ANALYSIS OF THE COMPOSITE AGS PANEL

In this chapter, the composite AGS panel is analyzed in detail for different type of critical loading conditions. The main analysis is done for Load Case 2, which is the optimum design model given in Chapter 6. Stress analysis plots for all the grids are given for different angles, thus maximum stresses are shown on FE model. Inter-laminar stresses are also studied for aforementioned load case. Additionally buckling modes are shown for 10 modes for the optimum model.

5.1 Modeling

There are several types of plane elements exist in commercial FE Analysis programs. In our case, the compatible element type and a tool, which composite materials can be defined, was the selection criteria for FEA program. Most of the conventional FEA programs store and uses data on the basis of laminate materials. On structural parts, this type of representation makes model extremely complicated and layers becomes overlapping. MSC. Patran store the data of the structure in terms of its constituent layers which makes the model easy to check and understand. Patran as a pre-processor has a composite tool (Figure A.3) which can be used to create orthotropic properties for laminae and composite laminate.

The input cards used to model 2D composite AGS panel consist of FE element and material property definitions. The element library for 2D shell modelling provides CQUAD4 element in Nastran, which defines an iso-parametric membrane-bending or plane strain quadrilateral plate element. The properties of the n-ply composite material laminate are defined with PCOMP card and then translated to MAT8, which defines the material property for an orthotropic material for iso-parametric shell elements.

Furthermore, the main idea for modeling of the composite AGS panel is using quadrilateral elements or quadrilateral elements mixed with triangular elements, where it is impossible to mesh with quadrilateral elements. As it is given in literature study chapter, researchers tried different types of elements which can cover the

behavior of composite AGS panel as a skin and stiffener, but the main purpose of this thesis is to define a model using existing FEA 2D quadrilateral element types that can simulate the behavior of the surface and stiffeners of the composite AGS panel.

Correspondingly, the following decision is about how to input the stiffness parameters into the nodes representing the AGS plate. As it is known, FEA programs use elements to make connection between nodes. In our case, this connection could be possible in three ways using 2D quadrilateral elements;

- The first way is to model stiffeners as separate quadrilateral elements that one edge nodes are connected to the nodes of the surface and to model surface elements, mesh should follow the stiffener geometry. Disadvantage of this type of modeling is thickness of the stiffeners is actually not modeled physically. Thus, global model geometry is altered and accuracy of global and local buckling analysis is lost.
- The second way is to model a geometry which stiffeners are also modeled as 2D projection on x-y plane, by the aid of the layer based modeling, the stiffener geometry would include the surface and stiffener layers altogether through the lattice geometry. It gives better accuracy for the buckling modes of the AGS panel but continuity on skin layers and the stiffener layers are lost.
- The third one, which is found suitable for our model, is to model stiffener and the surface as separate elements, and the pattern of the mesh should follow the lattice of the AGS plate. This application uses duplicate elements approach. The most important advantage of this type of definition of the AGS panel, an engineer is able to model physical body with exact geometry without losing any stiffness parameters. Therefore, optimization or especially the local and global buckling analysis of the same structure can be conducted without losing the accuracy and the insight of the quadrilateral element behavior.

5.2 Meshing

There are two types of elements available to model 2D panel. CQUAD4 and CTRIA3 elements can be used separately or together as described below. All

CQUAD4 mesh is selected over CQUAD4 and CTRIA3 mixed mesh due to behavior of CTRIA3 element. The location where CTRIA3 element needed is mostly critical locations, thus stiffer behavior of the CTRIA3 element will result in higher stresses than actual value.

5.2.1 Quad elements

The Composite AGS panel is modeled with CQUAD4 given in Figure 5.1. This two dimensional elements, which are called plate or shell elements, represents areas where one of the dimension is small compared to the other two. This elements calculate the membrane stiffness of the two dimensional elements using two different theories. First one is plane stress, which the normal stress σ_z , and the shear stresses, σ_{xz} and σ_{yz} , directed perpendicular to the x-y plane are assumed to be zero. The loads are assumed to be applied uniformly over the thickness of the plate. Second one is the plane strain, which the strain normal to the x-y plane, ϵ_z , and the shear strain γ_{xz} and γ_{yz} , are assumed to be zero. This assumption is valid for the dimension of the structure in one direction is very large in comparison with the other two directions of the structure.

This element has four nodes and five degrees of freedom (DOF) per node. The DOF include three translational and two rotational degrees of freedom. The rotational DOF not included at each node is along the axis normal to the plane defined by the element sides which intersect at each other.

CQUAD4 Meshed Full Panel

CQUAD4 Meshed One Cell

Figure 5.1: The Composite AGS panel is modeled with CQUAD4.

5.2.2 Quad and tria elements

The Composite AGS panel is modeled with CQUAD4 and CTRIA3 given in Figure 5.2. CQUAD4, CTRIA3 are the general-purpose plate elements capable of carrying in-plane force, bending forces, and transverse shear force. This family of elements is the most commonly used 2-D elements in the MSC Nastran element library.

The elements are elastically connected to only five of the six degrees of freedom at each of its grid points. The element does not provide direct elastic stiffness to the sixth degrees of freedom, i.e., the rotation about the normal to the surface of the element. Therefore, if a grid point is attached to the CQUAD4 elements only and all of the elements are in the same plane, then the rotational degrees of freedom about the surface normal have zero stiffness. This zero stiffness results in a singular stiffness matrix and the job fails. In addition to that due to behavior of the triangle element it is not recommended to use near the interest region or critical points.

CQUAD4 and CTRIA3(green) Meshed Full Panel CQUAD4 and CTRIA3(green) Meshed One Cell

Figure 5.2: The Composite AGS panel is modeled with CQUAD4 and CTRIA3.

5.3 Boundary Conditions and Loading

5.3.1 Load case 1

Compression load is applied for Load Case 1. All edges are constrained in T3 direction and in addition to that opposite side of the force applied edge is constrained in T1 direction and one node on the corner fixed all DOF. Force is applied on x axis as 276 N/mm as given in Figure 5.3. This type of constraint mechanism simulates compression testing of panel. After the application of the force, displacement value is

taken from the solution on the applied force direction, which is used instead of the force along x direction.

Figure 5.3: The Composite AGS panel LC1 BC and loading.

5.3.2 Load case 2

Biaxial loading and shear loads are applied for Load Case 2. All edges are constrained in T3 direction. Additionally bottom edge of the AGS panel is constrained in T2 direction and one node on the corner fixed all DOF. Compression force on x axis is applied as 150 N/mm and compression force on y is applied as 60 N/mm. Shear force is applied on all the edges which is about 175 N/mm. This type of constraint mechanism (Figure 5.4) simulates bi-axial loading test of panel.

5.3.3 Load case 3

Biaxial loading, shear loads and the pressure is applied for Load Case 3. The boundary conditions for LC3 are the same as the LC2 given in Figure 5.4. In addition to that 0.08 MPa pressure loading applied inside of the panel that grids are laying on the surface.

Figure 5.4: The Composite AGS panel LC2 BC and loading.

5.3.4 Local 3D case

Inter-laminar shear stresses are checked using 3D model, and critical locations of the 2D FE model are taken. When a laminate is thick or when the load path and state of stress in the structure is three dimensional, solid elements are more appropriate. CHEXA element, which defines the connections of the six-sided solid element with eight grid points, is used to model local area. A laminate composite shell or solid can be analyzed by using the PCOMPLS entry referencing a CHEXA element, but only in SOL 400.

There are couple of tricks need to be decided and controlled by user. Solid elements contain stiffness only in the translation degrees of freedom at each grid point. Typically v_{13} is provided in data sheets but Nastran input field is for v_{13} . Ply thicknesses entered should be sum of a total laminate thickness which equals to the element thickness. Nastran does not check this for user.

Displacement and rotations are taken from the solution of the 2D FE LC2 solution. T1, T2, T3, R1, R2 and R3 values are applied on the boundary nodes of the grid and skin CHEXA elements as can be seen with red color in Figure 5.5.

Figure 5.5: The Composite AGS panel Local 3D BC and 2D nodal displacement application regions.

5.4 Solutions

5.4.1 Linear static

MSC Nastran uses linear solver which is named SOL101. The static analysis using Nastran allow analyst to analyze and design linear structures subjected to time invariant loading. The simulation of the necessary structural properties is performed using equations by MSC Nastran. The behavior of the structure is placed inside these matrix equations. The rows and columns of the matrices contain the model definitions (elements, properties, loads, etc.) and displacement sets are assigned to each degree of freedom (DOF) by Nastran.

The static equilibrium of the finite element model can be shown in matrix form in equation (5.1).

$$[K_{gg}]\{u_g\}=\{P_g\} \quad (5.1)$$

Where $\{u_g\}$ represents the global displacement set, which is the top level set, $[K_{gg}]$ is the global stiffness matrix and $\{P_g\}$ is the vector of explicit loads or implicit loads applied to the grid points. The stiffness matrix $[K_{gg}]$ is formed by generating and assembling the stiffness matrices for all of the elements.

For linear analysis, MSC Nastran plate elements assume classical engineering assumptions of thin plate behavior,

- The deflection of the mid-surface is small compared with the thickness
- The mid-surface remains unstrained (neutral) during bending. (This applies to lateral loads, not in-plane loads.)
- The normal to the mid-surface remains normal to the mid-surface during bending

5.4.2 Buckling

MSC Nastran uses linear solver which is named SOL105. Global and local instability modes of composite AGS panel are analyzed using Nastran solver. The buckling solution of the plate is assumed to be in linear range so that yielding of the structure and change of force direction are not included in the solution.

Linear buckling analysis using finite elements defines two stiffness properties which are differential stiffness and linear stiffness. The difference between two of them is differential stiffness that is constructed from higher-order terms of the strain-displacement relationships. The question comes into mind when instability behavior of the structure occurs, how can the compressive and tensile axial loading affect the linear stiffness matrix? Thus, differential stiffness matrix represents the linear approximation of softening (reducing) the linear stiffness matrix in the case of compressive axial load, and stiffening (increasing) the linear stiffness matrix in the case of a tensile axial load. The element stiffness matrices are denoted as below in equation (5.2).

$$\begin{aligned} [k_a]_i &= \text{linear stiffness matrix} \\ [k_d]_i &= \text{differential stiffness matrix} \end{aligned} \tag{5.2}$$

The differential stiffness is a function of the geometry, element type, and applied load. The global linear stiffness matrix can be represented as equation (5.3).

$$[K_a] = \sum_i^n k_{a_i} \tag{5.3}$$

As linear stiffness matrix, the global differential stiffness matrix can be represented as equation (5.4).

$$[K_d] = \sum_i^n k_{d_i} \quad (5.4)$$

The overall system stiffness matrix is represented as equation (5.5).

$$[K] = [K_a] + [K_d] \quad (5.5)$$

Total potential of the system must have stationary value to achieve static equilibrium, a can be given in formulation (5.6).

$$\frac{\partial [U]}{\partial u_i} = [K_a]\{u\} + [K_d]\{u\} = \{0\} \quad (5.6)$$

where u_i is the displacement of the i^{th} degree of freedom.

Finite element model has finite number of degrees of freedom, although structures have infinite number of degrees of freedom in the real world. The number of buckling approximation of the structural behavior is proportional with the number of degrees of freedom of our model. It is formulated as in equation (5.7).

$$P_{cr_i} = \lambda_i P_a \quad (5.7)$$

Thus it gives the equation 5.8,

$$|[K_a] + \lambda_i [K_d]| = [0] \quad (5.8)$$

The above form of problems is called as eigenvalue problem. Once λ_i values are obtained, the buckling load can be calculated using equation (5.7). In addition to that λ_i values are the scale factors by which the applied load P_a is multiplied to generate the critical buckling loads P_{cr_i} .

In general, only the first two or three buckling loads are of any practical interest. The structure will fail prior to reaching any of the higher buckling loads other than first buckling load. MSC Nastran can perform buckling analysis on any or all of the loading conditions but it should be noted that it is valid for small deflections and elastic range. If it is an axial loading condition, applied load can be multiplied by the eigenvalue to obtain the buckling load.

5.5 Analyses Results

5.5.1 Displacement of the composite AGS plate

Resultant displacement plots are plotted to make a sanity check. Results coming from different type of loadings should give logical and physically correct displacements. Three load cases are shown on Figure 5.6.

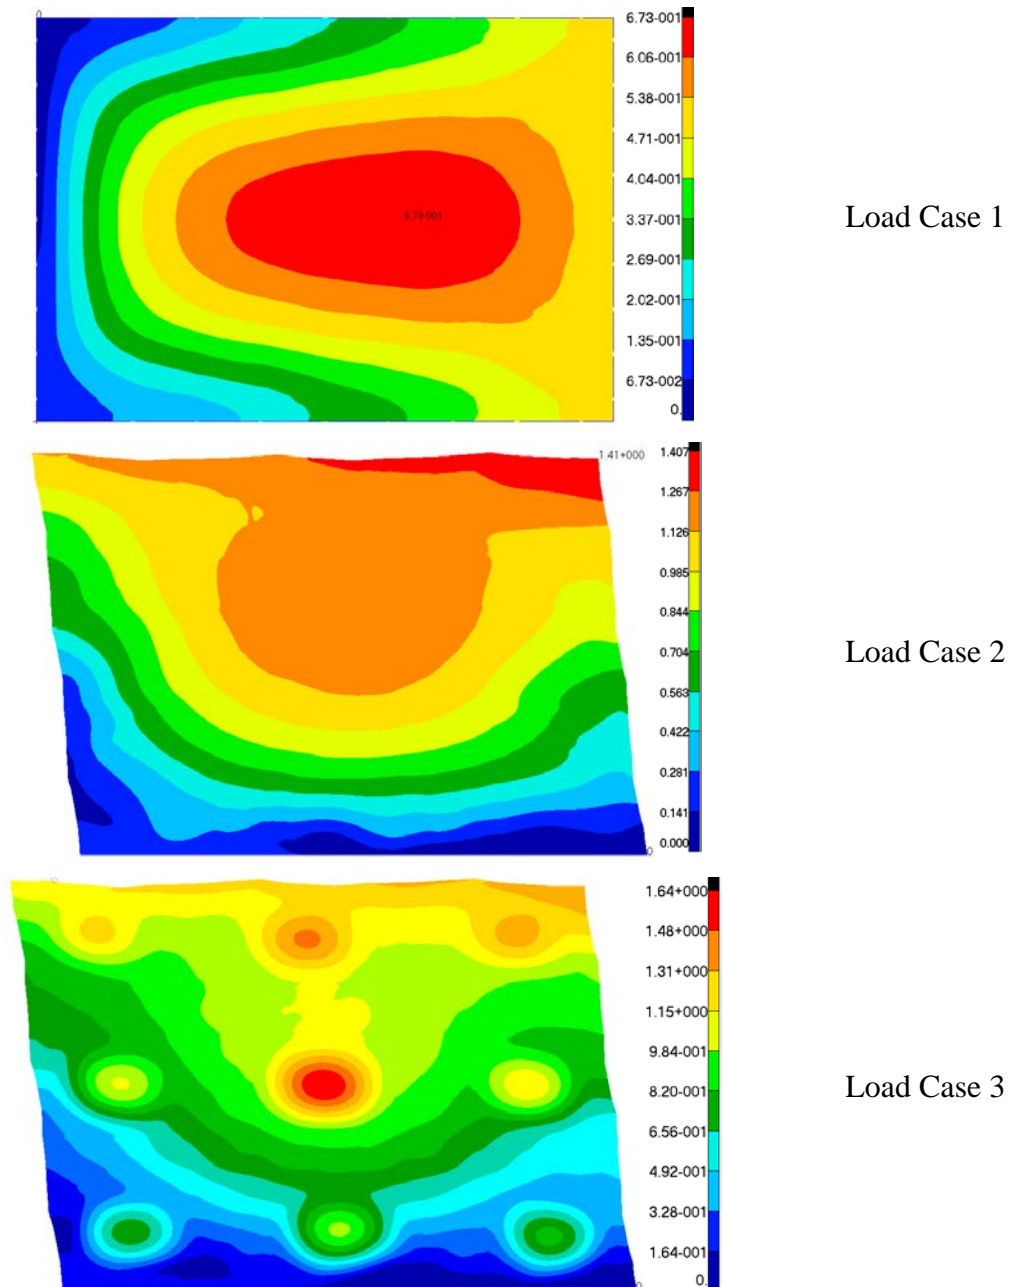

Figure 5.6: Displacement sums of the composite AGS plate for different load cases.

5.5.2 Stress distribution along stiffeners

Stress distribution along stiffeners is checked for the optimum model (Load Case 2). LC1 and LC3 stress distributions are given in Figure A.1 and Figure A.2 . FE model stresses has to be taken along the ribs which are 35° , -35° , 0° and 90° . It is necessary to note that elements that have maximum stresses near boundaries are disregarded, thus maximum on the spectrum is because of boundary effects. 35° direction stresses is given in Figure 5.7. Compression stress 226 MPa is shown as maximum stress on the rib.

Figure 5.7: Maximum ply stresses (MPa) along 35° direction (Load Case 2).

-35° direction stresses are given in Figure 5.8. Maximum stress is tensile, 211 MPa, along -35° rib direction. Main load carrying components are UD fibers, thus plots of the stresses are selected according to UD fibers along the ribs. Stress values are checked also for tensile maximum but not plotted, because peak stresses are compressive.

Figure 5.8: Maximum ply stresses (MPa) along -35° direction (Load Case 2).

0° direction stresses are given in Figure 5.9. This direction gives the stresses for horizontal ribs. 156 MPa tensile stress is found as maximum stress on fiber direction. As it is stated in the previous plot compressive maximum is also checked but maximum is compressive stress.

Figure 5.9: Maximum ply stresses (MPa) along 0° direction (Load Case 2).

90° direction stresses are given in Figure 5.10. Maximum stress is shown as tensile, which is 141 MPa. The stress is near the nodal location which is intersecting with 35° direction rib.

Figure 5.10 Maximum ply stresses (MPa) along 90° direction (Load Case 2).

5.5.3 Stress distribution on the skin

Stress distribution along skin is checked for the optimum model (Load Case 2). Skin stresses are higher at the boundary locations due to perturbation of the constraints and loading. Therefore, middle cell of the plate seen in Figure 5.11 is consistent but around the edges disturbance show itself by the stress contours. For the entire load cases skin is just giving its shape and protecting the ribs from environmental effects, thus skin material does not fail before the grids.

Figure 5.11: Maximum ply stresses (MPa) along 0°, 90° and 45° direction (Load Case 2).

Figure 5.11 (continued): Maximum ply stresses (MPa) along 0°, 90° and 45° direction (Load Case 2).

5.5.4 Inter-laminar stresses on 3D model

σ_{33} inter-laminar normal stress (peel stress) and σ_{31} , σ_{32} inter-laminar shear stresses are important in the study of delamination. Maximum stress value before failure for carbon fiber material is taken as 60 MPa from the previous experiences. Therefore Figure 5.12 and 5.13 show the inter-laminar stresses lower than 60 MPa. Maximum stress for the optimum model is near 21 MPa. 35° fiber direction stress is plotted for to compare the same location with 2D model. Maximum stress along the fiber direction deviates around %8, which is acceptable for the 2D-3D model validation.

35° fiber direction stress

Interlaminar normal stress (z direction)

Inter-laminar shear stress (σ_{31})

Inter-laminar shear stress (σ_{32})

Figure 5.13: Inter-laminar shear stresses (MPa) (Load Case 2).

5.5.5 Buckling modes of AGS panel

Linear buckling eigenvalue analysis is completed for the optimum model (Load Case 2). Once eigenvalues are obtained, the buckling load can be decided. In addition to that eigenvalues are the scale factors by which the applied load is multiplied to generate the critical buckling loads.

Ten buckling modes are solved by Nastran. Figure 5.14 shows the buckling modes. Global buckling behavior is not observed for optimum model. Thus, pocket (local) buckling occurs for all the buckling inside the grid cells.

Mode 1 - Eigenvalue : 1.0137

Mode 2 - Eigenvalue : 1.0968

Mode 3 - Eigenvalue : 1.114

Mode 4 - Eigenvalue : 1.1165

Mode 5 - Eigenvalue : 1.1212

Mode 6 - Eigenvalue : 1.1238

Mode 7 - Eigenvalue : 1.1261

Mode 8 - Eigenvalue : 1.1669

Figure 5.14: Buckling modes and eigenvalues for Load Case 2.

6. FINITE ELEMENT OPTIMISATION OF AGS PANEL

This chapter elaborates on the FE optimizations performed as part of the thesis project. As given in Chapter 5, Load Case 2 with the aforementioned boundary condition is used to create design model for panel optimization. Several optimizations were carried out for different configurations of the composite AGS panel.

6.1 Msc Nastran Optimization – How it works?

The composite AGS structure is improved through a design process by using MSC Nastran. Design optimization process searches for optimal or “the best” structural parameters and the searching operation uses some mathematical approaches to yield improved design.

An important concept of optimization is design sensitivity analysis, which gives the connection between the change of structural responses and changes in design parameters. These design variables or parameters can be anything depending upon analysis objective which is thickness, width of stiffeners and dimension of one cell lattice pattern for our case. These parameters affect the material failure behavior and buckling conditions, thus the rate of change is called design sensitivity coefficients. This sensitivity approach is the main information to perform optimization by MSC Nastran. Therefore, the current state of the optimized design is understood by using FE Model results and sensitivity gives an idea which way to look for an improved design. This algorithm is very useful especially for two or more design variables included in the optimization due to increasing number of possible solutions (analyses).

There are idealized statements to construct a design model:

- Design objective is the statement of what an improved means.
- Design constraint constitutes certain bounds, which the response of the system does not exceed.

- Design variable (side constraints) describes how the design might be changed and the meaning of a suitable variation.
- Design space is the definition of mathematical region over which design variables, objective, and constraints. Design space contains the local minima, which is the acceptable solution but can be more than one. As it is improvement of the design model, a unique solution is the goal of optimization.

The important thing for FEM based optimization, analysis results that are used in each cycle of the optimization is directly connected to the constructed FE Model. Thus, any mistake on meshed finite element model may lead to inaccurate and misleading results.

FEM optimization user has to know some limitations. MSC Nastran uses a numerical optimizer which is trying to find maximum or minimum depending on the objective, which has to be defined explicitly. Design model definition will result in a bound on responses and design variables, and this limits and objectives are directly used in the optimization cycle.

Numerical optimization algorithms that rely on gradient information are called “gradient based”. The basic optimization problem statement can be given as the mathematical expression,

\mathbf{X} needs to be found as minimum or maximum (Equation (6.1)).

$$F(\mathbf{X}) \text{ objective} \quad (6.1)$$

which is subject to inequalities given in equation (6.2).

$$\begin{aligned} g_j(\mathbf{X}) &\leq 0 \quad j = 1, \dots, n_g \text{ inequality constraints} \\ h_k(\mathbf{X}) &= 0 \quad k = 1, \dots, n_h \text{ equality constraints} \\ x_i^L &\leq x_i \leq x_i^U \quad i = 1, \dots, n \text{ side constraints} \\ \mathbf{X} &= \{x_1, x_2, \dots, x_n\} \text{ design variable} \end{aligned} \quad (6.2)$$

The objective function, which is the function of the set of design variables, needs to be minimized. Side constraints limit the region of search and the inequality constraints is satisfied if its value is negative by convention. Equality constraints give the exact optimal design.

The optimization algorithms in MSC Nastran belong to the family of methods referred to as “gradient-based”. This method helps to start numerical search for an optimum point, which is somewhere in the design space.

The beginning of the numerical search process is to find a direction. The process of searching continues while small steps in each of the design variable directions are taken. The mathematical concept is called first-forward finite difference approximation of a derivative. It is given as for single independent variable in equation (6.3),

$$\frac{df(x)}{dx} = \frac{f(x+\Delta x) - f(x)}{\Delta x} \quad (6.3)$$

where Δx represents the small step taken in the direction x . The resultant vector of the partial derivatives, or gradient, of the function can be written as equation (6.4),

$$\nabla F(\mathbf{X}) = \begin{Bmatrix} \frac{\partial F}{\partial x_1} \\ \vdots \\ \frac{\partial F}{\partial x_n} \end{Bmatrix} \cong \begin{Bmatrix} \frac{F(\mathbf{X}+\Delta x_1) - F(\mathbf{X})}{\Delta x_1} \\ \vdots \\ \frac{F(\mathbf{X}+\Delta x_n) - F(\mathbf{X})}{\Delta x_n} \end{Bmatrix} \quad (6.4)$$

which defines single components of the dimensional vector with partial derivatives.

The gradient vector goes in the direction of increasing objective function. Thus, the opposite direction of that gradient has to minimize objective function. The search of the minimum in this direction can be found with several different algorithms. The steepest descent, one dimensional search or Kuhn-Tucker conditions are useful algorithms for to conduct a numerical search in MSC Nastran optimization.

6.2 MSC. Patran PCL Functions

The PATRAN Command Language (PCL), which is a programming language, is used to create functions to be called directly from Patran, to create forms and widgets, to call functions from all areas of Patran including all applications, graphics, the user interface, and the database. The entire Patran user interface is driven by PCL.

The user interface system is integrated with PCL via callbacks. Thus, if a menu item selection or button click occurs, a PCL function is called to process the operation. All

the processing is also recorded in the session file. These commands may be entered interactively through the command line, or processed in session as stated above. The purpose of the session file, which PCL codes are written for the current session, is to allow Patran session to be recreated when the session file called.

The composite AGS panel has design variables that can be changed inside the loop of FEM Analysis and that cannot be changed due to need of appropriate re-meshing. There is couple of dimensions, i.e. stiffener spacing, rib width, is changed between optimization cycles using PCL functions. The main limitation to modify geometric dimensions following with re-meshing is altered by modified session files.

PCL functions are defined in files which can be created and modified with system level text editors. The first statement in a PCL function must start with the word FUNCTION. The last statement in a PCL function must be an END FUNCTION statement. “!!INPUT file” command, which is with two exclamation marks “!!” at the beginning of the line, executes the compiled file.

6.3 Design Model

A design model is an idealized statement of changes which might be made to the structure to improve its performance or response. In order to accomplish this, the word of improved design has to be defined.

Skin laminate layup for the composite laminate is modeled with [45/-45/0/0/0/90]_s. This sequence is taken from the historic studies on the AGS laminates and it is found to be most suitable for our case. It is also known that the thickness of the skin is the driving factor for weight objective. Therefore, knowing that 11 ply skin designs are possible the skin layup was limited to 11 plies. The skin ply angles were limited to 0°/45°/-45°/90°.

The stiffener angle, width and height of the ribs are derived based on the historic preliminary sensitivity studies of the objective function. Rib layup is UD along 0°/+35°/-35°/90°. 0° is called as longitudinal ribs, +35°/-35° is called as helical ribs, and 90° is called as circumferential ribs. Minimum dimensions for longitudinal ribs are started from 3.8 mm and for helical and circumferential ribs are started from 3 mm. Grid spacing is also started from 184 mm and rib ply thickness is selected as 1

mm. Rib height is 28 mm at the beginning of the optimization. These parameters are given in Figure 6.1.

Figure 6.1: Rib design parameters at the beginning of the design cycle.

Skin lay-up sequence is given in Figure 6.2.

Figure 6.2: Skin lay-up for design model of composite AGS panel.

In analysis, we are usually guaranteed a unique solution, while more than one solution may be possible in design optimization. Therefore the mathematical region consisting design variables, objective, and constraints are defined in the design space by convention.

Rib height is selected as the design variable in each design cycle. As optimum cycle rounds, dimensional change affects the plate offset value that has to be defined in CQAUD element type. Therefore plate offset is also defined as design variable for all the cycles and it is updated continuously.

Design limits (constraints) are selected as first ply failure, rib crippling and Euler buckling. Design model corresponding to a redesign of the composite AGS panel is basically for weight minimization. It gives allowable structural variations subject to limits on structural responses (stress).

A further manufacturing constraint comes from the pre-preg tow manufacturers. If one has to use the off-the-shelf available materials then the available tow-preg widths are 1/8", 1/4", 1/2", 1", etc. The lowest widely available width is one eighth of an inch. The data was also included into the optimization limiting the achievable grid widths. Using a set width of tow-preg it becomes necessary to use ribs of equal widths as well.

6.4 Optimization Results

Since structural optimization is an iterative process, numerical criteria must be established to determine when the overall process has converged. A convergence check is made immediately following the structural analysis. In reality, two methods are used to test for convergence with respect to overall design cycles by Nastran. These methods are denoted as soft convergence and hard convergence. Soft convergence is based on the results of the approximate optimization, while hard convergence is based on finite element analysis results.

Hard convergence check is used for the composite AGS panel optimization. Hard convergence compares the results of this most recent finite element analysis with those from the previous design cycle. Since this test compares the exact results (within the limits of the finite element analysis) from two consecutive analyses, the conclusions are said to be based on hard evidence. Since this test is conclusive, this is the default test for determining whether or not to terminate the design-cycle process.

Converged results are read from the *.f06 file which consists all the result data about optimization. Patran PCL function is used to create design models. Rib width and rib spacing are constant during optimization cycle of each design model as can be seen

from Figure 6.3. Optm_3 with 205.89 mm rib spacing design model is selected as the optimum model as shown Table 6.1 and detailed FEM analysis are conducted for it.

Weight of the panel, buckling modes under Load Case 2 and first ply failure mode were the main constraints and selection mechanism is driven for this design constraints. Optm_3 with 205.89 mm rib has lower weight when it is compared to other models and also buckling mode shows pocket buckling at the same time with first ply failure. Rib crippling and Euler buckling as design constraints are not expected for the current design model.

Table 6.1 Optimization Results for various design models (Length units are in *mm* and Weight unit is *kg*.)

7. FABRICATION OF ADVANCED GRID STIFFENED (AGS) COMPOSITE STRUCTURE

The AGS composite plates are manufactured using carbon fiber and epoxy resin system. The main purpose of this chapter is to find a manufacturing methodology using resin infusion system. Although manufacturing of simple composite panels using resin infusion technique is hard to check and control the variables affecting the structure quality, it is cost-effective and allows integral manufacturing with one-go processes.

The most important thing about the fiber reinforcement is to understand one-dimensional strengthening process. This process depends on the fiber material orientation in the appropriate amount of matrix material. In addition to that, shape of the structural component must be achieved and bonding between the matrix and the fiber has to be developed. There are several methods of forming process but these methods should not damage the fibers and has to ensure homogeneous distribution of the fibers in the matrix.

7.1 Material System

The fiber material is selected as carbon fiber material. Carbon fibers are widely used for airframes and engines and other aerospace applications. Torayca T700S carbon fiber is selected manufacturing of skin and ribs due to highest strength, standard modulus fiber available with excellent processing characteristics for filament winding. Rib fibers are UD carbon tow, which consist of an untwisted bundle of strands that in turn consist of a collection of more than one continuous carbon filament (12k filament). It is very important that the strands in the tow are maintained under even tension because uneven tension markedly affects later processing. Uneven tension in processes filament winding can result in strands sagging and becoming entangled. Importantly, fiber tension in the finished component will vary significantly, reducing the reinforcing efficiency.

There are large range of resins can be used for resin infusion process. The resin system that is used EPIKOTE™ is supplied as two component, which is hardener (EPH 04908) and epoxy (EPR 04908). The selection of the resin system is important for manufacturing, because of its viscosity for the molding and the required fiber/volume fraction. The decision of resin viscosity can be different for low fiber/volume plates (around %40) and higher fiber/volume fractions. Aerospace structures mostly uses higher fiber/volume fraction, thus viscosity of 500 centipose is more suitable for application.

The injection pressure for the resin system is also important fact. Higher pressures can cause reinforcement distortion, incomplete fiber wetting and voids within the tow bundle, lower pressure can also cause voids between tows. The usual process to observe the resin flow is to use computer models, but if sufficient experience is provided behind the resin material assumptions may meet the expected results. The basic idea is to find the highest pressure that can be used without causing significant imperfection.

7.2 Tooling System

7.2.1 Aluminum block tooling

Tooling for the manufacturing of composite AGS panel is designed to meet requirements needed for vacuum infusion process and resin transfer molding (RTM) process. Closed mold is designed to provide pattern of AGS panel. The geometry of the structural part is determined by the mold but uncontrolled expansion of the mold material is not expected at the high temperatures. Thus aluminum male and female molds are manufactured with precise geometrical dimensions as can be seen in Figure 7.1.

Female mold is designed to lay fiber bundles inside the grooves and female mold is designed to consolidate laid fibers at the phase of filament winding, thus the percentage of the fiber volume can reach up to %55.

Fiber, resin system and aluminum has different coefficient of thermal expansion, which affects volume expansion at elevated temperatures. The pattern of the panel shown in Figure 7.1 has to be preserved by taking into account effect of temperature on tooling material.

Figure 7.1: Female and male Aluminum molds.

7.2.2 Expansion block tooling

Expansion block tooling includes silicone rubber mold. This mold is produced from the shape of the aluminum male mold for one cell and 3D printed hard plastic for 2*2 cells (Figure 7.2). Silicone rubber material is selected as Silastic® M RTV and Silastic® S Silicone Mold-making Rubber, which is a two-part base and curing agent.

Figure 7.2 Silicon rubber molds - One cell and 2*2 cells.

The curing agent is thoroughly shaken before use. 100 parts of Silastic® S Silicone Mold-making Rubber base and 10 parts of curing agent are weighed out in a clean container. Accurate weighing is essential, as inaccuracies can cause a significant decrease in the performance of the cured rubber (the base to curing agent ratio must be between 100:9.5 and 100:10.5). Compound is mixed until the curing agent is completely dispersed in the base and a uniform color is obtained. Entrapped air is removed in a vacuum chamber, allowing the mixture to completely expand and then collapse. After three additional minutes of vacuum, the mix should be inspected and is used if free from air bubbles. A volume increase of two to three times occurs on

vacuum de-airing of the mixture, so a suitably large container is chosen. Afterwards, this mix is poured into pattern geometry. This high-strength, tear resistant product cures at room temperature around 14 hours.

Silicone rubber is the material of choice for expansion blocks manufacturing. It is very suitable for molding and therefore high precision at low cost can be achieved (no machining required). Presently, silicone rubber is available with various molding viscosities and hardness properties. Ideally the hardness of the rubber is dependent on the ease of removal from the male mold and the manufacturing process. Soft rubber is found to be easier to remove from the manufactured panel and from the male mold.

7.3 Manufacturing Steps for Composite AGS Panel

7.3.1 First trial of composite ags panel manufacturing

Aluminum block tooling is used very first time of manufacturing process. The idea of using a mold with grooves is to place fiber bundles coming from carbon fiber tow as shown in Figure 7.3. The logic of placing is the same as filament winding operation under tension. The tool is covered with four vertical stick, each time only one fiber bundle is laid into the groove and then it is turned around the appropriate stick to maintain the tension of the fiber. This operation is repeated till all the grooves filled with the carbon fiber.

Figure 7.3 Dry/Hand lay-up fiber bundles using carbon fiber rolls.

The process of winding is completed by hand and 85 layers for each grid are laid into grooves by the aid of small rollers. The next process is to take these fibers out without disturbing orientation, angle and height of the ribs. The challenging part of

the work is that fiber layers are consolidated and trial of removal requires considerable amount of force. Although it is hard to preserve the shape in the mold, fibers are taken out from the aluminum mold as shown in Figure 7.4.

Figure 7.4 Removal of aluminum mold and silicon block placement.

Afterwards, silicon blocks, which have the exact dimensions of space between the grids, are put between block patterns. This method has issues when placing silicon rubbers between grids because side surface of the rubbers are not slippery. Again, considerable amount of force is needed to place rubbers into correct position and preserving the assembly stable is not really possible. The idea to use rubbers is to control dimensioning in curing process of resin fiber system but process could not be accomplished at the middle phase and new methods are considered as explained in second trial.

7.3.2 Second trial of composite ags panel manufacturing (1*1 cell)

The second trial of composite AGS panel manufacturing is successfully applied. The logic of fiber placement is same as aluminum block tooling application. All the fibers laid into grooves one by one for each rib direction by the aid of dry/hand lay-up.

The main advantage of using silicon rubber molds is that the same mold can be used at the phase of dry/hand lay-up and curing, thus fiber pattern of ribs is preserved as shown in Figure 7.5. Extra fibers turned around the sticks providing required tension are cut at the edges by the aid of scissor.

Figure 7.5 Dry/Hand lay-up fiber bundles using carbon fiber rolls.

The mold and laid fiber is ready for to apply manufacturing method derived for composite AGS plate. Skin laminate layup for the composite laminate is cut with laser controlled cutting machine. An 11 plies are placed for $[45/-45/0/0/0/90]_s$ sequence and they are put on the upper side of mold that ribs fibers can be seen(Figure 7.5). Thereafter, metal plate, which everything placed on it, is cleaned by solvents and acetone in a closed room with air conditioning. This operation is repeated 3 times with minimum 15 minutes intervals. Peel ply is placed onto the metal plate and mold with skin is turned upside down on the peel ply (Figure 7.6). Peel ply is folded on the bottom side of the mold to prevent resin coming out and allow air trapped in resin coming out. Then, semi-permeable membrane, which is based on a high-tech textile membrane permeable to gas but impermeable to resin, is used to cover all around with peel ply.

Figure 7.6 Semi-permeable membrane and peel ply placement.

Breather fabric is used to provide continuous air suction under pressure and also to soak up excess resin coming from the mold. It is placed on the metal mold and it

covers the periphery of the mold as shown in Figure 7.7. Afterwards, tacky tape is placed to the edges of the metal plate to seal the edge of the vacuum bag to the mold. A vacuum hose, which is covered with semi-permeable membrane to stop excess resin closing the suction system, is used to provide a pressure difference using vacuum pump. Then, vacuum foil is sealed to the edges where tack tape is placed. As it can be seen in Figure 7.7, extra tacky tape is used to increase the surface area that touches the mold. Therefore, the edge surfaces of the mold has to be covered by the vacuum foil for to get homogeneous pressure distribution all around and for not to harm vacuum foil. Inlet and exit feed tubes are positioned on the mold and the around the mold.

Figure 7.7 Vacuum assisted resin infusion system for composite AGS panel.

100 parts of resin and 30 parts of hardener are weighed out in a clean container. Compound is mixed until the hardener is completely dispersed in the resin and a uniform color is obtained. Entrapped air is removed in a vacuum chamber, allowing the mixture to completely expand and then collapse. After three additional minutes of vacuum, the mix should be inspected and is used if free from air bubbles. A volume increase of two to three times occurs on vacuum de-airing of the mixture, so a suitably large container is chosen. Afterwards, resin pot is connected to vacuum assisted resin infusion system. Vacuum pump is connected to vacuum hose which is going in the vacuum foil (Figure 7.8).

Vacuum assisted resin infusion system is started by opening the vacuum pump. Absolute pressure is set to 55 mbar. The vacuum in the vacuum bag or resin trap is

measured with a vacuum gauge and the reading is relative to the external atmospheric pressure, in units on the barometric scale. This relative measurement is called gauge vacuum and is the pressure difference below the atmospheric pressure. Thus the absolute pressure in the vacuum bag or resin trap is equal to the current atmospheric pressure minus the vacuum pressure in the same units and the driving force for the resin to get into the part is the difference in the same units between the atmospheric pressure and the absolute pressure in the bag.

Resin infusion process for 1*1 cell takes about 1 hour and afterwards 17 hours passed in room temperature with vacuum. Then, assembly is put into oven 75 °C and it stays 4 hours in the oven. After curing cycle mold is removed from the cured CRFP plate as shown in Figure 7.8.

Figure 7.8 Vacuum assisted resin infusion system and cured composite AGS panel.

7.4 2*2 cell Composite AGS Panel Manufacturing

1*1 cell Composite AGS Panel is manufactured successfully at the second trial. Accordingly, 2*2 cell Composite AGS Panel manufacturing is done by the same method. The differences are resin hose inlet locations, the mold manufactured for 2*2 cell pattern and frame with long enough bolts to simplify winding process as can be seen in Figure 7.9. Continuous placing of the reinforcement material is designed for the specific cases. This process logic is almost similar to the filament winding applications. The process basically involves the winding of continuous fiber by the help of the sticks or long enough bolts. The important thing when placing fibers is to provide enough winding tension, winding angle, desired ply lay-up and fiber/volume fraction.

After dry/hand lay-up all the plies to their expected position, the lay-up is prepared for curing. Vacuum bag is applied over the bottom surface of the rubber mold. Consolidating pressure applied during infusion by evacuating the space under the bag. Breather fabric is used to transmit gases under pressure and it allows gases to flow from all over the part to vacuum fitting. Bleeder fabric is also used to soak up the excess resin, especially at the end of the stiffeners. Tacky tape, which is made from butyl rubber, used to seal the edge of the mold with the plastic vacuum bag.

The mold itself can expand when it is heated to higher temperatures. Thus it has to be taken into account so reinforcement from the edges and corners can be applied to prevent shape distortion. Metal frames are placed around the silicon rubber mold to restrain volume expansion at elevated temperature.

The important thing about bagging, homogeneous distribution of the consolidation pressure has to be applied to the part and at the same time the trapped gases in the lay-up has to be removed from the system. After injection, the mold is put into oven.

Figure 7.9 Dry/hand lay-up winding process and metal frames placed at the ends of mold.

Thermoset resin is used for matrix material. These resin system has to be cured at certain temperature, thus sufficiently high service temperature of the composite can be ensured. Our composite material is cured in an oven under a vacuum bag (Figure 7.10). The part is heated by convection of heat from the fan-forced air circulation. Heating is begun immediately; target temperature may not be reached for several hours due to thick parts. If resin viscosity is too high, air can be entrapped inside the plate. Fiber waviness is another significant problem occurs when placing fiber onto the mold. This can result in a significant loss of strength and stiffness. It can be avoided by maintaining the correct level of filament tension during dry/hand lay-up.

Figure 7.10 Dry/hand lay-up winding process and cured composite AGS panel.

The most difficult part of the closed mold system is the resin flow, which cannot be observed. In addition to the viscosity of the resin, permeability of the carbon fibers is another issue. If too much material used in the cavity of the mold, the permeability of the fibers will change, dry spots can be observed at the end of the infusion process.

Another important difficulty is to find the suitable locations for resin injection. Preform that is laid inside the mold needs uniform distribution of the resin through the thickness. Therefore, gating which refers to the resin distribution system should be decided for infusion. There are different types of gating mechanisms can be used that are line gates, point gates, and perimeter gates. All of them have different advantages. For our case point gates are used to infuse the stiffeners and skin fibers.

The important thing the remember resin follows the perimeter of the part. The uncontrolled behavior of the resin can result in dry spots due to air entrapment. The solution of this problem is to choose appropriate gating system, otherwise when resin reaches the closer edge of trimmed structure, it flows faster than the flow at the perimeter. Thus resin closes all edges around and leads to trap-off of air.

The advantages of the vacuum assisted resin infusion system used in this chapter, excellent dimensional control, controllable surface finish, reproducibility, reduced labor cost, elimination of the use of autoclave. This process can be used for complex stiffener geometries especially for small dimensions which require precise dimensional control on the material surface.

8. CONCLUSIONS AND RECOMMENDATIONS

This chapter contains the conclusions and the recommendations resulting from the performed work.

8.1 Conclusions

Analysis, optimization and manufacturing of AGS panel, which consists of perpendicular longitudinal (x-axis) and horizontal (y-axis) stiffeners, and angled stiffeners that cross x-axis with ± 35 degree and $[+45/-45/0/0/0/90]_s$ configuration for the skin lay-up is accomplished in the thesis. FE design and analysis of the composite AGS panel is conducted using Msc. Patran/Nastran using 2D and 3D elements for different type of stress analyses. Analytical assumptions are used for the nodes to create a region for transition of the material properties. FE optimization design model is created for different configurations by the aid of Patran PCL functions, which provides macro-like commands. Wolfram Mathematica codes are used to generate Msc. Patran PLC function inputs, which create Msc. Nastran input for the optimization cycle.

Analytical models are derived from the classical laminate theory. Material property and failure strength of intersecting nodes and transition regions are calculated using symmetric laminate assumption. Equivalent properties, which are originated from the UD material properties, are then used on FE modeling definitions.

The different failure modes of a stiffened composite plate are also studied in detail by FE Analysis methods using Nastran as a solver. Stress analyses of the boundary edges do not give logical and consistent results. These studies show that the efficient utilization of material highly depends on the buckling failure mode and first ply failure of the composite AGS plate. Therefore failure in buckling mode is local (pocket buckling) due to geometric orientation of grids. Additionally first ply failure and buckling load is set equal to each other as a result of the optimization. Critical locations for Load Case 2 are found to be mostly on 35 degree grid fibers. Skin

material thickness has significant effect on the buckling modes of the composite AGS panel.

Manufacturing of the AGS panel use methods of resin infusion process under vacuum and quality evaluation of the AGS panel is conducted macroscopic methods to check. Designed methodology for manufacturing gives reliable material with low cost production technique. Resin infusion for advanced composite structures is highly desired due to its low cost and less time spent for manufacturing, although uncontrollable variables exist in infusion process. Therefore selected method provides an excellent method when it is compared to studies done so far. Fiber volume is reached up to 55% and dimensioning of the manufactured part complies with the design model. Material quality evaluation is done by macro pictures of the manufactured material by human eye. The quality for the grids is beyond the expectations, although small dimensions of the grids make things difficult.

8.2 Recommendations

Analysis, optimization and manufacturing of AGS panel needs development as all the studies on the literature. There are number of revisions and validations on all the steps of the composite AGS plate project.

First of all, 2D FE analysis elements can be extended to thick composite elements or 3D analysis of the whole composite plate to validate the results coming from this thesis with the more detailed analysis.

Secondly, optimization cycles used in Nastran codes can be extended to genetic algorithms, thus a better converged optimum can be obtained from optimization cycle. Design constraints might give other optimums; therefore a new design model can be analyzed in detail.

Thirdly, theoretical model creation cycle might be validated by the relevant tests or historical test data if possible for the material properties derived.

Furthermore, manufacturing of the AGS composite plate needs input for resin inlet and its location changes for the different numbers of cells. Accordingly, an algorithm might be developed to locate resin inlets for different type of dimensioning and geometries.

In this way, quality control tests to get fiber volume fraction is needed. Deficiencies that are possible due to manufacturing methods have to be inspected in material testing and inspection laboratory.

It could also be said that, manufacturing of the composite AGS panel with dry/hand lay-up is time consuming. Thus, a filament winding method might be designed to automate winding phase which will allow manufacturing fuselage structure.

Subsequently, material testing and microscopy might be designed for to validate the analysis results and material quality.
